

Affective Choice: A Learning Approach Toward Intelligent Emotional Behaviour For Ubiquitous Computing Applications

A thesis submitted to the
University of Dublin, Trinity College,
in fulfilment of the requirements for the degree of
M.Sc. in Computer Science

Michael Morrissey

Ubiquitous Computing,
Department of Computer Science,
Trinity College, University of Dublin

May 2006

DECLARATION

I, the undersigned, declare that this work has not previously been submitted as an exercise for a degree at this or any other University, and that, unless otherwise stated, it is entirely my own work.

Name: Michael Morrissey

Date: 30/05/06

PERMISSION TO LEND AND/OR COPY

I, the undersigned, agree that the Trinity College Library may lend and/or copy this thesis upon request.

Name: Michael Morrissey

Date: 30/05/06

Acknowledgements

I would like to thank my project supervisor Mads Haahr for his interest and advice during the development and demonstration of this thesis.

I would also like to thank my excellent parents, for the love and support they have provided throughout my last 20 years of education.

I especially want to thank Máire, for all her love and support.

Abstract

This thesis presents the relevant research undertaken in the design, development and implementation of an EEG based reusable affective computing interface, concomitant with its implementation, evaluation and use.

The "Affective Choice" system is an affective computing system using a learning based approach to derive intelligent emotional behaviour. The system will attempt to detect and describe a user's affective patterns (emotional cues), and learn to equate these emotional patterns with the user's desired actions through a reinforcement-learning framework.

Detectable affective patterns include obvious expressions of emotion, such as a smile, a frown, a relaxed or angry voice, but are also evident in physiological changes in autonomic nervous system activity, such as brain wave patterns, accelerated heart rate or increasing skin conductivity. The "Affective Choice" system will attempt to detect and model, a user's physiological patterns, together with feedback of their use of an application, in order to learn to predict desirable choice, on behalf of the users. The aim of this project is to provide a reusable affective interface which, when utilised in suitable applications, will provide an additional "emotional channel" for human computer interaction. This will allow an application to learn to provide the user with a desirable choice without explicit interaction, therefore increasing ubiquity.

EEG	Electroencephalogram
MEG	Magnetoencephalogram
EMG	Electromyogram
GSR	Galvonic Skin Response
fMRI	Functional Magnetic Resonance Imaging
PET	Positron Emission Tomography
BVP	Blood Volume Pulse
ECG	Electrocardiogram
ERP	Event Related Potentials
RHH	Right Hemisphere Hypothesis
VH	Valence Hypothesis
Prosody	Term used to refer to speech elements such as intonation, pitch etc.

Chapter 1: Introduction

An Affect is the external expression of emotion attached to ideas or mental representations.

The "Affective Choice" system is an Affective Computing system using a Learning based approach to derive intelligent emotional behaviour. The system will attempt to detect and describe a user's affective patterns (emotional cues), and learn to equate these emotional patterns with the user's desired actions through a reinforcement-learning framework.

Detectable affective patterns include obvious expressions of emotion, which we, as humans, are very effective at recognising, such as a smile, a frown, a relaxed or angry voice. The expression of these emotional affects plays a large part in how humans interact and communicate. For instance, it is impossible to be certain that a statement is meant to be sarcastic without the accompaniment of a sarcastic tone of voice or facial expression. Statements such as "It's not what he said but the way he said it" also attest to the importance of emotion expression in human communication.

Affective emotional patterns are also evident in physiological changes in autonomic nervous system activity, such as accelerated heart rate or increased skin conductivity and in the central nervous system, the brain. The "Affective Choice" system will attempt to provide application developers with a prototype affective user interface. This interface can be used within any application to detect and model its user's physiological patterns, in order to provide awareness of a user's state of mind, or to allow affective signals to be used to directly control some functionality of the system.

1.1 Background

The vision and idea behind affective computing was first introduced by Rosalind Picard in a technical report from MIT's Perceptual Computing Department in 1995. The interest that this idea sparked led to the formation of the Affective Computing Group, at MIT Media Lab, lead of course by Rosalind Picard, who further outlined her ideas and thinking behind affective computing in her acclaimed book "Affective Computing" (Rosalind W. Picard 1997 [45]). Since then the Affective Computing Group have continued to pioneer the research in this area, producing a steady stream of innovative and novel projects over the past ten years.

The area of affective computing relates to human computer interactions where a device or system has the ability to react appropriately to its user's emotional state. Such a device must have the ability to sense at least one of the many affective signals exhibited by an emotional human user and, most importantly, correctly categorise or identify the particular mood or emotion that that affective signal might represent.

Sources of these affective or emotional signals include, facial expression, tone of voice or speech patterns, gestures, body language, etc. Other possible sources of such information can be derived from a subject's use of established computer interfaces, such as mouse movements, number of mouse clicks, patterns and indeed the force with which keys are pressed. This type of information would for instance exhibit whether a user was frustrated with, or very tentative and unsure of their control of a computing system. These sources of affective information, in fact directly represent our unrelenting failed human attempts to communicate our frustration to our standard computer systems. It seems that no matter how aware we are that these expressions of affect are falling on deaf ears, this does not diminish our attempts to communicate to computers in this way. This provides an excellent illustration of how essential and fundamental this method of communication and interaction is to us. It also provides a very strong argument for the development of affective user interfaces, so much so that it seems strange that these obvious manifestations of attempted interaction have to date been almost completely ignored or overlooked.

However, most of these signals are in some ways unsuitable as sources of affect in a ubiquitous, mobile or wearable system, either by not providing enough information to derive effect, by being difficult to measure and process or simply by not reflecting

the emotions of a user. For this reason it may be an advantage to use some less obvious affective signals that are not so generally used for communication, such as those emanating from our central and peripheral nervous systems. The most accessible of these effective signals include ECG, EEG, EMG, GSR, BVP and others. All these signals are examined and explained further in Chapter 4: .

In order to recognise patterns within these affective signals and to correctly categorise such patterns as emotions, moods etc. it would be helpful to have some knowledge and understanding of what exactly emotions are, what their purpose is and where they come from. Unfortunately, as discussed in Chapter 2: there is no clear definition of emotion, nor can emotions be objectively observed. Instead we are left deciding between models of emotion derived from behavioural, psychological, or physiological characteristics, so called ‘components’ of emotion, coupled with their subjective descriptions. Despite the difficulties of finding textbook definitions for what exactly emotions are and where they come from, there is no argument about their existence and importance. It is better that we seek to enhance our understanding of emotions, rather than struggle to define them. Using this approach allows us to develop affective computing systems, able to provide applications with an insight into their user’s emotional state, without having to get bogged down in the detail and philosophical debate that surrounds the study of human emotions.

1.2 Motivation

Coming from a background in computer applications and software engineering into the exciting area of ubiquitous computing with its fresh new ideas, interfaces and visions for the future of human computer interaction, it is immediately clear how many of these visions are still without answers. The implementation of the majority of such ubiquitous systems very much involves starting from the ground up, as, to date, there is a severe lack of suitable middleware and API’s in the area. The focus of my research is in developing a ubiquitous user interface, which addresses some of the visions of ambient control set out in the ubiquitous computing paradigm, whereby, intelligent devices in our environments can act in a desirable manner on our behalf without requiring explicit user interaction or physical control. Clearly, this ideal presents many challenges which require attention.

I believe that the area of affective computing (through the use of emotionally intelligent user interfaces) is set to offer solutions to a possibly limitless number of computing applications, and in particular has potential as an alternative user interface in the domain of ubiquitous computing. There are huge problems inherent in ensuring that ubiquitous computing systems (especially agent systems acting on our behalf behind the scenes) act only in desirable and efficient ways. I believe that, through the use of intelligent affective interfaces these problems can be much more easily and effectively addressed while preserving the defining ambient nature of such systems.

1.3 Project goals and Outcomes

The aim of this project was to research, design and build a simple, reusable and easy to implement, affective interface system. This thesis presents the outcomes of this project whose main goal was to develop a proven affective interface which can be easily implemented in order to provide an additional “emotional channel” for human computer interaction. This affective interface will be shown to enable the development of applications that can make desirable choices on behalf of its user (based on the user’s affective state, or mood) without the need for physical actions or explicit interaction. It is the intention that this affective interface can be easily reused as a component of future ubiquitous applications.

1.4 Outline

When attempting to define a new human computer interface it is crucially important to understand the background and research related to both the human and technology aspects of the desired interaction. This thesis, therefore, explores the relevant research relating to human emotion and affective signal processing that is required to competently undertake decisions regarding the design and development of this affective user interface, concomitantly with details of its implementation, evaluation and use. The following paragraphs provide a short overview of each chapter.

In Chapter 2: I briefly describe some of the current projects being undertaken in the field of affective computing, in order to provide comparison to the work presented in this thesis.

In Chapter 3: I set out to define and understand what an emotion is, and the limitations and problems inherent in attempting to measure, understand or even categorise an emotion. I examine various models of emotion derived using different mechanisms. This chapter also examines the main research in the area of human emotion, outlining the conflicting models, opinions and viewpoints expressed in this difficult area.

In Chapter 4: I describe and contrast the different sources of affective signal, concentrating on sources evident in the central and peripheral nervous systems. I conclude this study with the reasons for my choice of EEG alone to be used for the measurement and classification of a user's affective state.

In Chapter 5: I further examine the suitability of EEG in the study of emotions, and examine the relevant research related to brain function, emotion and the processes and components of EEG recording. I conclude with justification for the use of EEG as the basic component of the affective interface system.

In Chapter 6: I outline the final design, implementation and use of the affective interface system. Class diagrams and functional description of the components of the interface are also presented in this chapter.

Finally in Chapter 7: I describe an evaluation of the Affective Choice System, and conclude by outlining the successful outcomes of the project

Chapter 2: State of the Art

Research in the area of affective computing was pioneered in the late 1990's by MIT's Affective Computing Group, headed up by (Rosalind W. Picard 1997 [45]). This group still lies at the forefront of research and work in this area. In order to demonstrate the highest degree of development in this field I will outline three of the most current research projects being undertaken at MIT's media lab. The three projects outlined below include, The Social-Emotional Prosthetic, The Platform for Affective Agent Research and The HandWave Bluetooth Skin Conductance Sensor.

2.1 The Social-Emotional Prosthetic for Autism Spectrum Disorders

(R. el Kaliouby, et al. 2006 [32])

The Social-Emotional Prosthetic is a novel wearable device that perceives and reports on so called social-emotional information in human-human interaction. The system is designed to annotate real-time human interaction in order to assist communication in the natural environment. The intended application of this system will be to help individuals, diagnosed with Autism Spectrum Disorder (whose traits include social impairment), to be able to increase their awareness and perception of communication in a natural environment in order to maximise their ability to learn and develop in social settings.

According to the research this project brings together and expands upon recent advances and methodologies in affective computing, wearable computing and real time machine perception. The system gathers this social-emotional information using a small wearable camera and other sensors, such as skin conductance sensors. These sensors are combined with machine vision and emotion perception algorithms that provide real-time emotion annotation of a human-to-human interaction. The system analyses the facial expressions and head movements of the person with

whom the wearer is interacting, using mechanisms based on Kaliouby's model for the inference of affective-cognitive signals from head and facial movements (R. el Kaliouby July 2005 [31]). According to the authors, the wearable platform records natural face-to-face interactions, applying machine perception algorithms, which help identify the features of a social interaction and predict how that interaction should be perceived.

2.2 The Platform for Affective Agent Research

(W. Burleson, et al. 2004 [7])

This platform was built for the sensing and interpretation of several aspects of a user's nonverbal affective information. It is also designed to enable appropriate responses to be simulated through an expressive agent (a graphical 3d expressive humanoid agent). The platform consists of several multi-modal affective sensors, a real time inference engine, a behavior engine, and an expressive agent which operated inside a graphical virtual environment.

The platform's architecture treats its user's affective signals as inputs which are mapped using probabilistic and rule-based modeling to one of several outputs. The inference mechanism incorporates machine learning to tailor itself to a particular user's affective signals, this is however an offline process that requires designer intervention. The aim of the platform is to enable multiple channels of affect to be monitored and analysed in order to better understand how affect is communicated. Their multi-modal sensor system consists of a pressure mouse, a wireless skin conductivity sensor, a posture analysis chair (uses a TekScan pressure sensor), and a facial action unit analysis module hooked up to IBM's blue eyes infra-red sensitive camera system, to provide face and head tracking. This system expands upon the earlier work (A. Kapoor, et al. 2001 [33]) which used just facial and postural information.

This platform is seen as a general-purpose tool that can be used for research in several areas, including how to design an affective learning companion, and how to increase our basic understanding of empathy and emotion in order to promote human-agent interaction leading to affective

machine expression. See also work on The Affective Learning Companion (Winslow Burleson and Rosalind Picard 2006 [8]).

2.3 The HandWave Bluetooth Skin Conductance Sensor

(M. Strauss, et al. Oct 2005 [51])

The HandWave is a small, wireless networked, skin conductance or galvanic skin response (GSR) sensor, especially designed for use by the Affective Computing Group at MIT in their affective applications. It is used to detect information related to emotional, cognitive, and physical arousal of mobile users. According to the group, GSR is the most reliable measure of arousal (see valance/arousal model in section 3.2.4) in human emotion. As noted by the author, the majority of existing affective computing systems have made use of inflexible sensors that are physically attached to supporting computers, in contrast to this HandWave allows truly mobile interaction. Its use of Bluetooth affords the device an additional degree of flexibility by providing ad-hoc wireless networking capabilities to a wide variety of Bluetooth devices, including PDA's and mobile phones. I have highlighted this device to show how affective computing systems can be easily integrated into, and used to provide affective user info to applications of ubiquitous computing, and as a direction for future work involving the system presented by this thesis.

The HandWave device is currently being used in a variety of different applications at MIT, including:

Learning Companion. A relational agent that supports different meta-cognitive strategies to help students overcome frustration. Using affective mirroring: the agent subtly mimics the user's various aspects of the user's affective expressions (Winslow Burleson and Rosalind Picard 2006 [8]).

Collective Calm. A multiplayer, biofeedback, tug of war video game that teaches groups of players how to relax within a competitive

environment and learning to cooperate as part of a team. The team that collectively relaxes the most wins the game.

2.4 Affective Choice, in relation to state of the art

The affective choice system is inspired by the work outlined above, but has been designed uniquely as an interface to be used to provide ubiquitous applications with emotional information describing the affective state of their users. The system will allow ubiquitous applications to act and react appropriately according to their user's affective state, without explicit physical interaction. It is also the intention that this interface can be used to provide more than one type of affective signal, and that it can be configured for a wide range of applications. In order to facilitate this the Affective Choice system uses EEG to measure its user's affective state. This is an approach which is not taken in any of the affective computing applications described above, even though the area of cognitive science attests to the importance of the brain in controlling emotions. The use of EEG to derive affective state is, in my opinion, a much more flexible arrangement, as it allows the same system to be used to sample the array of heterogeneous emotional and physiological artefacts evident in the brains ERP's. Using EEG signals also allows the system to be configured to recognise conscious and unconscious brain wave patterns, enabling the interface to act either as an affective choice system (where events are triggered on behalf of a user, based on their affective signals), or as a brain controlled interface (where a user can consciously trigger events just by 'thinking about it').

Chapter 3: Emotion

*”Everyone knows what an emotion is, until asked to give a definition”
(Beverly Fehr and James Russell 1984 [21])*

We are emotional beings, so much so that our emotional state plays an important role in how we experience and interact with our environment. Emotion directly affects our decision-making, perception, cognition, creativity, attention, reasoning, memory, and how we learn. It has been shown that the ability to express our emotion is integral to our ability to communicate with each other, through facial expression, tone of voice or body language. (F. D. Ross [47]) found that stroke patients who cannot properly identify or generate the affective emotion that accompanies speech, experience severe interpersonal difficulties and problems expressing themselves. For most, the detection of emotions is intuitive during interaction. Strange, then, that there is as yet no accepted scientific method of detecting when or what type of emotion a subject is experiencing. There is even disagreement concerning the classification of emotional states into types. As (Beverly Fehr and James Russell 1984 [21]) succinctly put it ”Everyone knows what an emotion is, until asked to give a definition”

3.1 Defining Emotion

Emotions cannot be objectively observed, directly measured or wilfully elicited. Only subjective definitions of emotions are possible. We can describe what it feels like to have an emotion, and we do, using words like happy, sad, anger, jealousy, love and fear. So when we attempt to describe or define emotion we find that we cannot without returning to these subjective definitions.

What we can measure and describe are some of the behavioural & physiological components or affects of emotion, such as facial expressions or heart rate and brain

responses. A broad definition of emotion was emphasised by (P. Kleinginna and A. Kleinginna 1981 [35]) once they had completed reviewing and classifying over 100 varying and inconsistent definitions.

"Emotion is a complex set of interactions among subjective and objective factors, mediated by neural/hormonal systems, which can: (a) give rise to affective experiences such as feelings of arousal, pleasure/displeasure; (b) generate cognitive processes such as emotionally relevant perceptual effects, appraisals, labelling processes; (c) activate widespread physiological adjustments to the arousing conditions; and (d) lead to behaviour that is often, but not always, expressive, goal directed, and adaptive"

(P. Kleinginna and A. Kleinginna 1981 [35])

This definition cautiously outlines four important components of emotion outlined in able 3-1. This consensual definition is in fact so consensual that some authors (Frank Enos 2003 [20]) have dismissed it as lacking a point of view and therefore think it irrelevant. Others believe that a definition of emotion is impossible as emotions are hypothetical constructs, being neither observable nor measurable. Despite this Kleinginna & Kleinginna’s model is still widely accepted as a definition of the main components of emotion.

A. Kleinginna & P. Kleinginna Components of Emotion	
Affective Components	Subjective Experiences such as Arousal, Pleasure, Displeasure.
Cognitive Components	Emotionally Relevant Perceptual Effects such as Appraisals, Labelling Processes etc.
Physiological Components	Physiological Functions, changes in peripheral and central nervous system
Behavioural Components	Behavioural functions such as facial expression, verbal and nonverbal communications and actions

Table 3-1: Components of Emotion (P. Kleinginna and A. Kleinginna 1981 [35])

However difficult it may be to find a suitable definition for what exactly an emotion is, nobody can deny the existence and importance of emotions. It is then, perhaps, more important that we seek to understand our emotions, how they work, how they affect us and their purpose, rather than simply trying to wrap them up in a suitable textbook definition.

3.2 Models of emotion

How do we know when a subject is experiencing a particular emotion? What are the basic emotions that the subject may be feeling? How do we model these basic emotions? These are all difficult questions without clear or definite answers. What we do know is that it is more likely that an emotion is present when there are simultaneous, complex changes in our subjective feelings, physiological states and behaviour. Lucky for us that these are things which can be measured, regardless of whether you consider them components of emotion or simply side effects of cognitive processing. Therefore we can assume that an emotion is being felt whenever recognisable changes occur simultaneously in a subject's affective state. How do we then categorise what emotion or type of emotion that our subject may be experiencing? To do this we first require a set of basic emotions to be defined. Armed with these basic emotions we can produce a model of our subject's emotional state.

A useful model would draw distinctive and reliable relationships between discrete emotions and their affective components. So that, for instance, when your heart rate rapidly jumps and you begin to shake, you are experiencing fear. Coming up with a good model of emotion is difficult as there are many affective channels through which it might be possible to model emotion. The main channels used to model emotion include: facial expression, vocal expression or voice modelling, signals present in the peripheral nervous system such as heart rate, temperature, GSR etc. and signals present in the central nervous system usually measured by EEG or MEG.

3.2.1 Basic Emotions

The definition of a set of basic emotions, also known as primary or fundamental emotions, is another area where there is no agreement. (T Turner A Ortony 1990 [1]) in their paper entitled “What’s basic about basic emotions?” questions the concept of basic emotions altogether, stating that there are no satisfactory criterion regarding what makes an emotion basic, and that the concept of basic emotion can not account for the large diversity of emotions.

Support for the concept of basic emotions comes from two differing schools of thought and relates to the origin and purpose of emotion. However, their conflicting ideas both lend credibility to the idea that there exists some set of basic emotions. These are the Social Constructionists or Cognitive Theorists and the Darwinian Evolutionary Theorists. The social constructionist theory states that adult human emotions depend upon social concepts and are learned throughout ones lifetime. Here basic emotions are attributed to the constant social learning which they believe will occur for all members of a particular species, regardless of culture. The Darwinian theorists suggest that basic emotions are selected by nature through a process of natural selection through their survival advantages. Here basic emotions are those, which are passed down by our ancestors, i.e. fear protects us from danger etc. Darwinian theorists also leave room for social learning to occur throughout the lifetime of a subject, but they believe it is control of the basic emotions that is being learned. (C Izard and S Buechler 1980 [28]) state that adult human emotions are the same as those found in animals and human infants with only rudimentary powers of consciousness, proving that cognition is not required for these emotions, that they are inherent in our makeup and that they don’t need to be learnt.

In order to describe the criteria for the definition of a set of basic emotions (T. D. Kemper 1978 [34]) outlined five criteria which he felt must be met in order for an emotion to be considered a basic emotion.(see Table 3-2 below), He also suggested four basic emotions: fear, anger, depression and satisfaction.

T.D. Kemper – 5 Criteria for Basic Emotions	
Evolutionary Basis	Must be evident or at least inferable in most animals
Cross Cultural	Must be universally evident in all cultures, independent of environment.
Ontogenetic	Must be evident in early development
Social Relational Basis	Must be a result of social interactions
Physiological	Must be associated with specific autonomic physiological changes

Table 3-2: T.D. Kemper – 5 Criteria for Basic Emotions(T. D. Kemper 1978 [34])

As outlined in (Michaela Esslen Pascual Marqui 2002 [40]) Kemper also classified the different methodologies employed in the definition of basic emotions. He highlights seven of the more important ones as: evolutionary, neural, psychoanalytic, autonomic, facial expression, empirical classification and developmental. Unfortunately for Kemper his criteria for basic emotions were not widely accepted and others kept defining their own set of basic emotions. As shown in (Michaela Esslen Pascual Marqui 2002 [40]) (see Appendix Table 0-1) between all of these diverse sets of basic components, we are able to extract a set of the most popular basic emotions, over which there seems to be agreement. These are:

Anger /Rage Fear/Anxiety Happiness/joy Sadness/Sorrow/Grief

Disgust

Surprise/Astonishment

(Paul Ekman 1999 [19]) who is a strong Darwinian theorist describes six basic emotions reflected in human facial expressions across several cultures. All six are in line with those above. Ekman et al, also support their findings with signals coming from the autonomic nervous system. These signals show that the basic emotions of fear, anger, sadness and disgust exhibit different and specific patterns in a subjects affective cues of heart rate and GSR (Skin Conductivity). This is very important for me as it lends support to the idea that by observing the affective patterns in GSR, heart

rate and other autonomic nervous system signals, a computer system is in effect gaining an insight into the emotional state of the user.

Although there is no consensus on the issue, basic emotions are said by some researchers to act as building blocks for more complex emotions. (C Izard 1991 [27, R Plutchik 1994 [46]) describe complex emotions (non-basic emotions) as being made up of mixtures or differing combinations of basic emotions, this view is also expressed by early work by (W.V. Friesen P Ekman 1975 [42]) where they suggested that “for example, smugness might be considered to be a blend of the two elemental emotions, happiness and contempt.” These emotions are generally referred to as compound emotions.

Building on this come the secondary emotions described by (A Damasio 1994 [14, J. LeDoux 1996 [36]). Secondary emotions or emotional memories are evident where orderly associations have been made between objects, situations and basic emotions. These are learned emotional responses, such that in some situations the retrieval of emotional memories of similar experiences are used to effect our actions in that situation. E.g. the memory of your emotional state after being involved in a car accident would cause a secondary emotion to be felt every time you sat into a car. Secondary emotions seem to be the basis of most irrational fears and phobias, where strong emotional responses are associated inconsistently with certain stimuli.

3.2.2 Vocal model of emotion

Models of emotion through vocal expression have been achieved using methods such as Prosodic modelling and Formant Synthesis. Prosody is the term used to describe elements of speech such as intonation, pitch, rate, loudness, rhythm, etc. Formants on the other hand refer to variable components evident in the frequency spectrum produced by an instrument or human voice. Formants are what give vowels their characteristic sound.

(Walter Sendlmeier Felix Burkhardt [22]) created a model for synthesising emotional speech. Burkhardt defines a number of modifiable parameters of speech, which when manipulated in the appropriate ways, can transform neutral speech (devoid of affect) into emotional speech.

The modifiable parameters are outlined as follows:

Pitch Height, Range:	Variation of pitch values.
Pitch Contour:	Changes to the pitch contours of syllables and whole phrases.
Flutter:	Flutter or jitter applied to all vowels.
Intensity:	Varying intensity applied to syllables.
Speech Rate:	Varying speech rate.
Phonation Type	Modal, falsetto, breathy, creaky, or tense voice .
Vowel Precision:	Formant target overshoot or undershoot.
Lip-Spreading:	Raising of frequencies of formants by a given rate.

Using this set of modifiable voice parameters Burkhardt set about conducting two experiments. The first experiment involved the systematic variation of selected acoustical features of human speech. The aim of this first experiment was to gauge the importance of certain acoustical features for vocal emotional expression. The second experiment was designed to investigate a greater feature set than was involved in the first, and also to distinguish between emotions that differ only by the extent of arousal present. The approach to the second experiment differs from the first, here a prototype spoken with an emotionally neutral condition is generated for each emotion and is then manipulated to further investigate the effect of modifying certain parameter features.

The results of the (Walter Sendlmeier Felix Burkhardt [22]) experiments outline a system that is capable of generating recognisable emotional expression through the measured variation of its modifiable parameters. From our point of view what Burkhardt has produced is a model of the emotions of fear, joy, boredom, sadness and anger which can be measured by identifying the existence of certain variations in the signals formants.

The results model of Burkhardt's first test taken from (Walter Sendlmeier Felix Burkhardt [22]) is outlined below, also see Table 0-2:

Fear: Utterances were judged as fearful when they had a high pitch, a broad range, falsetto voice and a fast speech rate or a speech rate according to the mixed model.

Joy: Utterances with a broader pitch range and a faster speech rate as well as modal or tense phonation are more often judged as joyful than the other characteristics. A lowered pitch sounds less joyful. Striking is the noticeable effect of vowel precision: A precise articulation enhances a joyful impression and an imprecise one reduces it. Joy produces the least dependable recognition rates.

Boredom: A lowered mean pitch and a narrow pitch range as well as a breathy or creaky voice results significantly often in an assessment of the stimuli as bored. Furthermore, a slow speech rate and an imprecise vowel articulation enhance a bored expression. For all these features the reverse modifications weaken the assessment of the stimuli as bored.

Sadness: The expression of sadness is revealed by a narrow range and a slow speech rate as well as a breathy articulation. Surprisingly, a raised pitch contour and falsetto voice also enhance a sad impression.

Anger: For anger there are few, but obvious results. A faster speech rate and tense phonation is judged by the majority as angry.

Another vocal model of emotion is outlined by (Jeremy Ang, et al. [2]), who investigate the use of prosody for the detection of frustration and annoyance in human computer dialog. The prosodic features that are used in the model include: speech duration and rate, pause, pitch, energy and spectral tilt. Speech repetition and correction along with the position in the dialog are also considered as emotional features. Their approach uses a brute force algorithm for classifying utterances into the categories of: neutral, annoyed, frustrated, tired, amused, other and non-applicable (contained no speech data). Their classification algorithm is based on decision trees.

The results of the study entitled, “Prosody-Based Automatic Detection of Annoyance and Frustration In Human-Computer Dialog” (Jeremy Ang, et al. [2]) show that their prosodic model can predict whether an utterance is neutral versus “annoyed or frustrated” with the accuracy, they say, on a par with that of inter-human agreement.

3.2.3 Emotion Models based on Facial Expressions

By far the most common models of emotion have been created by measuring facial expressions. This is perhaps the most intuitive one, due to the fact we use our facial expressions constantly to express our internal feelings, and as a universal method of communication. As infants, before we learn to speak languages we intuitively recognise emotions in those around us and intuitively communicate back. In fact there have been studies conducted on neonates (newborn infants) by (H Oster and P Ekman 1978 [41]) and blind infants and children by (Charlesworth and Kreutzer 1973 [10]) showing that the basis for facial expression as a medium of emotion expression is hardwired in us from the beginning as there is simply no time to learn this behaviour. This strongly supports the view of the Darwinian (evolutionary) theorists, who believe that basic emotions have evolved through a process of natural selection. The basis for this point of view was (C Darwin 1872 -1998 [16]) where he argued that all mammals show emotion reliably on their faces, and, therefore, it could not be an entirely culturally- learned phenomenon.

“...the young and the old of widely different races, both with man and animals, express the same state of mind by the same movement”
(C Darwin 1872 -1998 [16])

Ekman has been at the forefront of the study of human facial expression related to emotion. He was the first to show the existence of a universally, cross culturally recognisable set of human facial expressions, when he travelled to the most remote villages in the jungles of Papua New Guinea, and found that the tribesmen there could instinctively and accurately recognise and categorise his set of facial expressions by their appropriate emotions.

On the back of this Ekman postulated and set out to prove that there are a set of rules that govern the way we interpret facial expressions. From this he, along with Friesen,

produced perhaps the most popular and useful standardised model for the categorisation of the physical expression of emotions. This model, called the Facial Action Coding System (FACS) classifies every anatomic human facial expression.

FACS identifies combinations of over 45 different action units (AU's), which relate to the contracting or relaxation of facial muscles. It also outlines the rules for the reading and interpretation of these action units, which allow us to determine a subject's emotional state. An outline of these rules can be seen in the example below, which shows (P. Ekman & W. V. Friesen 1978 [24])'s FACS models for fear, happiness and disgust.

Fear = Action Units: One, two and four, or, more fully, one, two, four, five, and twenty, with or without action units twenty-five, twenty-six, or twenty-seven; the inner brow raiser (frontalis, pars medialis) plus the outer brow raiser (frontalis, pars lateralis) plus the brow-lowering depressor supercilli plus the levator palpebrae superioris (which raises the upper lid), plus the risorius (which stretches the lips), the parting of the lips (depressor labii), and the masseter (which drops the jaw).

Happiness = Action Units: Six and twelve - contracting the muscles that raise the cheek (orbicularis oculi, pars orbitalis) in combination with the zygomatic major, which pulls up the corners of the lips

Disgust = mostly A.U. Nine, the wrinkling of the nose (levator labii superioris, alaeque nasi), but it can sometimes be ten, and in either case may be combined with A.U. fifteen or sixteen or seventeen.

(See Figure 0-1 for illustrations of first 20 action units)

Human facial expressions have a powerful link with our emotions, so much so that the mere expression of emotion, whether made voluntarily or involuntarily, has an impact on our emotional state. (Silvan S. Tomkins 1962 [53]) proposed that the physical changes and sensations resulting from the facial expression of emotion, are in fact the source of the qualitatively different feelings of emotion. E.g., happy from sad, fear from anger etc. (R. Tourangeau and P.C.Ellsworth 1979 [54]) showed that because of what they called the 'facial-feedback system', an expression you do not even know you have, can create an emotion you did not choose to feel. It has also

been shown that when we experience a basic emotion, a corresponding affective signal is sent to the areas that control the muscles of the face. This is evident in stroke patients that have suffered damage to what is known as the pyramidal neural system. These individuals are seen to be able to laugh normally to a joke, but are unable to smile on command.

These arguments suggest that there may be a two-way link between the emotion centres of the brain and the areas that control facial expression and that they may even be controlled by the same areas or mechanism in the brain.

3.2.4 Multi-Dimensional/Continuous Model of Emotion

“As everyone knows, emotions seem to be interrelated in various but systematic ways: Excitement and depression seem to be opposites; excitement and surprise seem to be more similar to one another; and excitement and joy seem to be highly similar, often indistinguishable”

(Russel and Bullock 1985 [48])

So far in the models of emotion outlined I have been discussing emotions as discrete phenomena, i.e. it must be either joy or surprise that is being felt, and not a bit of both. Emotions however are not discrete but continuous. Because of this continuous nature of emotion we should search for a model that defines emotion within a space where any given emotional state can be represented. One such model was suggested by Wilhelm Wundt, a German psychologist who is generally regarded as being the founder of experimental psychology. Wundt suggested representing emotional experience in a 3-dimensional space, where each emotion would be represented by a measure of Valence, Arousal and Potency. He described valence as being the master dimension, and is the value used to represent a subjects general positive or negative emotion. Arousal or activation is used to represent a degree of a subjects psychological engagement, alertness, or excitement, with or about the object of the emotion. And finally potency is used to refer to the subjects sense of power or control over events. Potency is generally left out of most implementations of Wundt's model as emotion studies tend not to have the scope to necessitate its

inclusion. Instead a 2D model is used, this is called the 2D Valence/Activation model. This model has stood the test of time having been used extensively over the years by psychologists and researchers of cognitive human emotion.

Studies by (Russel and Bullock 1985 [48]) and their use of multi-dimensional scaling¹ has successfully shown the usefulness and adequacy of the 2D valence / activation model in describing emotion. The advantages of this model include its simplicity and its ability to show not only discrete emotional states, but to describe the distance between these discrete emotions.

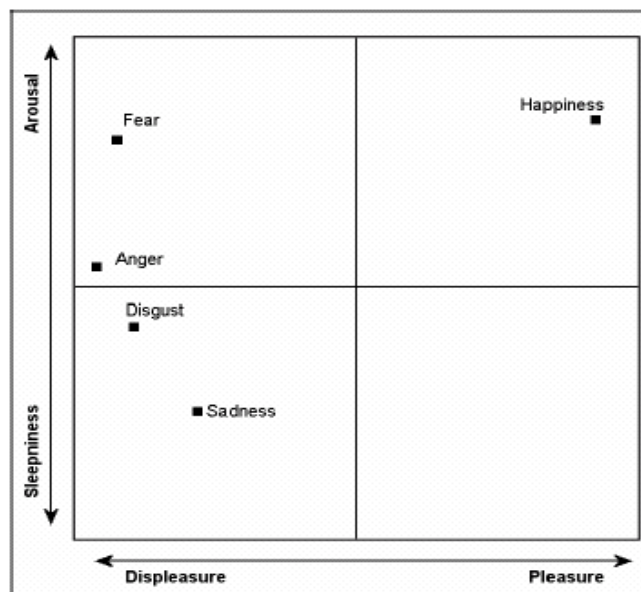

Figure 3-1: 2D Valence / Arousal Space and the distance between emotions
(Russel and Bullock 1985 [48])

(Russel and Bullock 1985 [48]) got adult subjects to sort a set of pictures of facial expressions, into “groups of people who feel alike”. The results of these groupings were modelled using a 2D valence/arousal space, and used to show the distances between a set of basic emotions. Their findings can be summarised as follows (also see Figure 3-1):

¹ Multi-Dimensional Scaling is a statistical procedure for determining the number of dimensions needed to adequately describe the distances among a set of objects – e.g. Emotions

Happiness was placed most distant from all other emotions measured and firmly with a positive valence.

Anger was placed close to disgust, but far from sadness and less far from fear.

Sadness was placed farthest from fear (among the negatively valenced emotions), followed by anger and disgust.

Fear was conversely placed farthest from sadness, followed by disgust and anger.

Disgust was placed close to anger and almost equidistant from sadness and fear.

Research undertaken by (P.Shaver, et al. 1987 [43]) provides evidence for the fundamental nature of the valence dimension regarding emotion. Their study concentrated on the categorisation of the meanings of a list of 135 emotion words. Subjects were again asked to place similar emotion words in the same category. Using this data, co-occurrence matrices were produced for each of the subjects illustrating the conceived similarity of the emotion words. These matrices were then aggregated so that each cell in the resulting matrix contained the percentage of subjects who categorised the two emotion words as being similar. Finally, this matrix was subjected to a hierarchical cluster analysis mechanism which further categorised the emotions into a hierarchical emotion space. (See Figure 3-2 below)

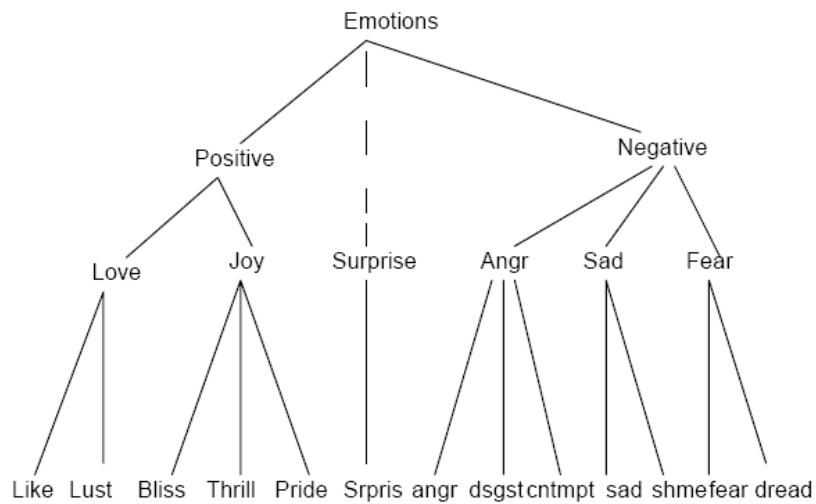

Figure 3-2: Simplified version of emotion hierarchy
(P.Shaver, et al. 1987 [43])

3.3 Conclusion

Emotions cannot be objectively observed, directly measured or wilfully elicited. Neither it seems can a definition be found for what an emotion is. Only subjective definitions of emotions are possible (how they feel to us). What we can measure and describe are some of the behavioural & physiological components or affects of emotion. A broad definition of these components of emotion was outlined by (P. Kleinginna and A. Kleinginna 1981 [35]).

In an attempt to better understand emotions, without requiring a concrete definition we turn to models of emotion and begin to agree upon a set of basic emotions. Regardless of whether you think that emotions are learned from birth, taught to us by society and culture, or have developed through the process of evolution getting passed down to us by our ancestors, it can be generally agreed that there exists some set of basic emotions. These basic emotions can be viewed as either the most universally taught emotions by society or those passed down in order to afford us with the best chances for survival. A generally agreed set of basic emotions, regardless of what mechanism or characteristics you use to define what a basic emotion should be, are outlined below.

Anger /Rage Fear/Anxiety Happiness/joy Sadness/Sorrow/Grief
Disgust Surprise/Astonishment

When given the task of recognising and correctly categorising the emotion felt by a subject by only measuring affective signals or components of that emotion, whether they be subjective accounts, facial expressions or vocal utterances, the choice of emotion model used is an important one. The simplicity, effectiveness and proven adequacy of Wundt's 2D valence/activation space as a model of human emotion and emotion in general make it my favourite in this regard. What's more, this representation seems intuitively closer to real feelings, and provides the ability of extracting emotion labels from a continuous representation of any sensed affective signal. It also allows for the searching of the valence/arousal space for clusters of emotion, which once identified could be used as the affective cue's to represent desired actions to be carried out on behalf of a user for the control of an application. This classification of affective spaces also lends itself nicely to the modeling of continuously - sensed emotional components such as those coming from the central nervous system. The remainder of this section concentrates on justifying my choice of the 2D valence/activation space with some supporting research and conclusion.

First of all, on examination of Figure 3-2 by (P.Shaver, et al. 1987 [43]) in support of the 2D valence/arousal model of emotion, the immediate logical separation of emotion into general positive and negative categories provides legitimacy to Wundt's view of valence as the master dimension representing a measure of an emotion's positivity or negativity. The presence of Surprise on the border line between positive and negative may suggest that it should not be categorised as an emotion but rather a higher level of arousal as it can be linked with both positive emotions and negative emotions such as joy and fear. This may also explain Ekman's difficulty with finding a specific pattern of autonomic nervous system activity for his basic surprise emotion.

In Figure 3-2 it can also be seen that the emotions at the intermediate level: love, joy, surprise, anger, sadness and fear, correspond closely both to the basic emotions described in (Paul Ekman 1999 [19])'s basic emotions and (Silvan S. Tomkins 1962 [53]) "Innate Affects". This shows that the hierarchical groupings of emotions

modelled by (P.Shaver, et al. 1987 [43]) using the 2D valence/arousal space correspond to those categorised using the discrete models of Ekman and Tomkins.

(R. Cowie, et al. 2001 [13]) also used a 2D valence/activation space to model and assess emotions derived from human speech. This model has stood the test of time having been used extensively over the years by psychologists and by researchers of human emotion, proving the models versatility.

Finally further analysis by (P.Shaver, et al. 1987 [43]) of their co-occurrence matrix using multi-dimensional scaling (See footnote1 p21) revealed the three dimensions first originally suggested by the founder of cognitive psychology, Wilhelm Wundt, valence, arousal and potency.

Chapter 4: Affective Signals

4.1 Sources of Affective Signals

The area of affective computing relates to human computer interactions where a device or system has the ability to react appropriately to its user's emotional state. Such a device must have the ability to sense at least one of the many affective signals exhibited by an emotional human user. Sources of these affective or emotional signals include, facial expression, tone of voice or speech patterns, gestures, body language, etc

What all these affective signals do have in common is that they are all conscious, communicative signals which we use continuously to express ourselves to others around us. They add meaning or affect to what we say and do, and as such they are used as descriptive tools, not just to communicate our own moods and emotions, but also to act out or mimic those of the people around us. In order to describe someone's reaction to a piece of news, for instance, we would mimic the facial expression and movements they made at the time.

We use many of our affective signals as natural, channels of expression in our everyday communications and interactions with others. Even though these expressions are easily observed and their meaning is generally understood, it cannot be clear whether or not they are being used to convey a subject's own emotions or to describe or mimic someone else's. Due to their descriptive nature all these affective signals can, at least to some extent, be faked and therefore do not always present an accurate measure of an individual's affective state. For this reason they are not considered to be suitable sources of affect for this work.

Other possible sources of such information can be derived from a subject's use of established computer interfaces, such as mouse movements, number of mouse clicks, patterns and indeed the force with which keys are pressed. This type of information would, for instance, exhibit whether a user was frustrated with, or very tentative and unsure of their control of a computing system. These sources of affective information, however, require a tangible interface to be present, such as the keyboard and mouse. This will not be the case for most ubiquitous applications.

I feel that it is more advantageous to use some less obvious affective signals that are not so generally used for communication, only reflect a subject's own emotions, and can not be easily or consciously manipulated. Such affective signals can be derived from the detection of changes in our central nervous system (EEG, MEG, MRI, PET) and peripheral nervous systems (EMG, GSR, Heart Rate). I will next examine each of these features in turn.

4.2 Affect from Peripheral Nervous System (physiological sensors)

4.2.1 Electromyogram (EMG)

An Electromyogram (EMG) is used to record the electrical activity of muscles. When a muscle is flexed or relaxed it produces an electrical signal. The strength of this electrical signal can be used as an indicator of the level of muscle activity, as the force with the muscle was contracted proves proportional to the strength of the electrical signal generated. Another advantage of EMG allows even minor muscular activity to be detected, even though it may not be apparent visually. This is especially true for facial expression recognition studies, where image recognition alone would overlook many of the important so called "tell tale" expressions. These "tell tale" expressions refer to the unconscious and uncontrollable facial expressions which manifest themselves automatically and often for only a fraction of a second. It has been shown that these muscle activity gives a very reliable measure of what a subject is actually feeling, and are very difficult or impossible to control or to fake.

Figure 4-1: Signals from EMG on the masseter muscle in micro-volts, indicating periods during which a subject was asked to express, no emotion, anger, hate, grief, love, romantic love, joy and reverence (J. Healey and R. W. Picard 1997 [25]).

EMG have mainly been used in facial recognition studies. Where only a few EMG sensors are used the sensors are often fixed to either the masseter (jaw muscle) to detect jaw clenching, an indicator of anger and frustration, or fixed to the frontalis (the muscle controlling the eyebrows) to detect particular movements of the eyebrows indicating, stress, surprise, bewilderment etc. However, having sensors affixed to the face proves very uncomfortable, and in affect hampers the very expressive movements which we are attempting to detect. For this reason the use of EMG, at least on facial areas, would not be ideal for a future wearable affective ubiquitous device.

4.2.2 Galvanic Skin Response (GSR) or Skin Conductivity Response (SCR)

GSR sensors are used to record the skins conductance over a small area. It is known that sweat glands (eccrine glands) present in the hands and feet show a galvanic effect. This effect is triggered not by thermoregulation, but by signals present in the sympathetic nervous system. These emotional signals such as arousal, are shown to cause near instant changes in the level of sweat in these glands, in turn affecting the skins conductivity in the area the glands are present. GSR measurements are generally identified as the most reliable indicators of a subjects arousal, therefore a GSR reading indicates the subjects level of arousal, on a scale from calm through agitated, to outright frustration and anger.

Figure 4-2: Signals from SCR in micro-Siemens, indicating periods during which a subject was asked to express, no emotion, anger, hate, grief, love, romantic love, joy and reverence (J. Healey and R. W. Picard 1997 [25]).

GSR is seen as the most popular affective signal used in determining emotion, and is used extensively by researchers in the area of affective computing. The actual sensors are generally fixed about two inches apart, either to the top and bottom of the middle finger or on the base of two adjacent fingers. This arrangement is quite comfortable and unobtrusive, however, it does not bode well when washing ones hands. On the down side, conductance readings are known to vary due to external factors such as ambient temperature and humidity, necessitating the addition of extra temperature and humidity sensors on the subject, used to negate these changes.

4.2.3 Heart Rate and Blood Volume Pulse (BVP)

Heart rate sensors are generally used to record inter-beat intervals or heart rate variability. These measures are generally used only as discriminatory factors in determining changes in a user's affective state and do not carry significant, affective or emotional information when viewed in isolation. This is due to the fact that it cannot be determined whether changes in inter-beat intervals are the result of physical activity, emotional stress, or the subject having just had a cup of coffee. It is only in relation to other affective signals that this type of information becomes useful.

Figure 4-3: Signals from Heart Rate in bpm, indicating periods during which a subject was asked to express, no emotion, anger, hate, grief, love, romantic love, joy and reverence (J. Healey and R. W. Picard 1997 [25]).

4.3 Affect from Central nervous system (The Brain)

4.3.1 Electroencephalography EEG

EEG is traditionally known as a medical imaging technique, used to measure and study electrical potentials caused directly by underlying brain activity. These tiny signals can be measured unobtrusively from the surface of the scalp using small metal electrodes, and are caused by the collective activation of neurons (brain cells) in the underlying brain areas. These activations cause local current flow between neurons, indicating that some type of mental processing is taking place in that area. The signal produced, along with the area of the brain from which the potential was measured, can be used to give an indication of the type of mental task being performed. EEG has been found to be a very powerful tool in the field of neurology and cognitive science, due to its capability to show patterns of electrical signals which can then be used to determine brain activity. The brain signals most apparent in EEG data emanate from the area of the brain directly beneath the scalp, the cerebrum, which contains the centres for movement initiation, conscious awareness of sensation, complex analysis, and most importantly the expression of emotion and behaviour.

These activity specific areas can be studied and measured using a technique known as event related potentials (ERPs). ERPs represent the averaged electric brain response to some form of sensory stimulation. Using this mechanism the reaction of different areas of the brain to chosen stimuli can be investigated in order to identify the various centres involved in reacting to these stimuli. For example using movement as a stimulus, the centres of the brain controlling this movement can be estimated, or by inducing the emotion of anger in a subject, the location of the source of this emotion can be approximated from the EEG signals. (this method is further described in Chapter 5:)

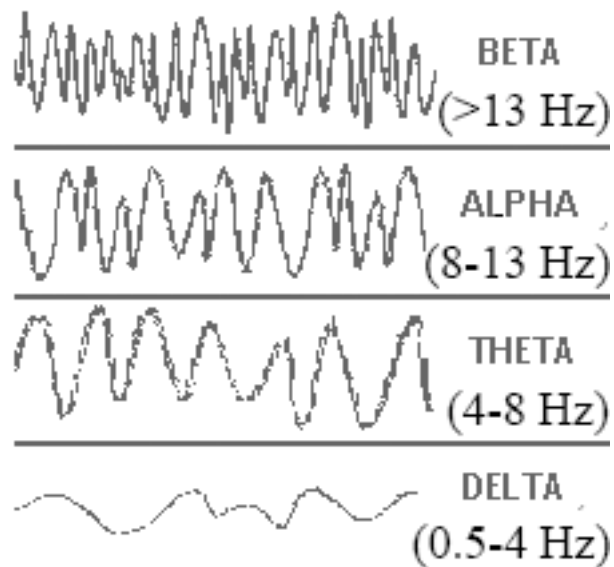

Figure 4-4: Brain wave samples indicating the four most dominant frequencies.

The patterns of output evident in an electroencephalogram are commonly referred to as brainwaves. These brainwaves have been classified into four main frequency categories, used here to indicate the most basic and obvious form of affective information evident from EEG signals. These categories can be used as a measure of a subject's alertness, simply by determining which brainwave is most dominant within the raw EEG data;

- Beta relating to a high level of alertness, involving cognitive processing, reasoning and concentration.
- Alpha relating to calmness, relaxation and problem solving.
- Theta relating to near sleep, daydreaming.
- Delta relating to deep dreamless sleep.

(Affect and EEG are examined thoroughly in Chapter 5:)

4.3.2 MEG, fMRI, PET – Other Advanced Brain Imaging Techniques

Magnetoencephalography (MEG), Functional Magnetic Resonance Imaging (fMRI) and Positron Emission Tomography (PET) - are all techniques of brain imaging, similar to EEG. MEG detects the same electrical signals detected by EEG, however it

measures the magnetic effects caused by the flow of current between neurons. This has an advantage over EEG signals in that it allows greater temporal resolution, allowing the source of electrical signals from within the brain to be more accurately located and modelled. However, it has one major drawback, in that it is highly susceptible to magnetic interference, even from the earth's magnetic field and requires shielding from this in order to correctly operate, making it unsuitable for this application. The fMRI measures blood flow in the brain. The thinking here is that active areas in the brain require more oxygen and energy to operate than inactive areas, therefore areas exhibiting increased blood flow are areas which are currently active. PET measures the emission of positrons, tiny particles which are emitted from a radioactively marked substance (generally oxygen, water or glucose) which must be first administered to the subject. Measurements of circulation of these positrons allow for the complete imaging of the body's systems, including brain activity and is generally used to identify a number of diseases. The use of fMRI and PET imaging in human emotion studies has increased significantly in recent years (A. R Damasio, et al. 2000 [15, M. L Phillips, et al. 1997 [44]), however, they are both unsuitable technologies for this application, as they are distinctly immobile and require prohibitively expensive equipment.

4.4 Conclusion

In this section I have outlined the main sources of emotion information most often used in affective computing systems. The majority of systems developed in this area use affective information derived from the peripheral nervous system, namely GSR, EMG and Heart Rate. However, in my opinion, the most promising of the affective signals discussed is EEG. Despite this, very few studies directly related to the area of affective computing have used EEG as a source of a subject's emotions, even though cognitive research has shown strong correlations between their subjects' brain activities and subjective emotions.

It is known that even the division of raw EEG data into the various brainwave frequencies, outlined above, can provide information regarding the levels of alertness of a subject. This, along with the measurement of event related potentials can be shown to provide accurate and dependable measures of a user's affective state, and

has been played a pivotal role in studies of brain asymmetry and emotion. Studies have shown that differences in the electrical activity between the two brain hemispheres can be used to predict emotional responses to various stimuli, including emotional stimuli, when measured from the frontal regions of the brain. The use of EEG in brain controlled interfaces also attests to the suitability of the technique in extracting and detecting cognitive information. The placement of scalp electrodes over different areas of the brain known to control certain cognitive processes may also allow for a choice of affective signals to be targeted and monitored for application specific purposes. It could also be argued the use of only scalp electrodes may be preferable over other affective sensors such as EMG or GSR which are most often affixed to the face and hands, because of the fact that we simply don't use our scalp for that much and the electrodes placed there wouldn't really get in our way. For these reasons and others outlined in Chapter 5: I have decided to use EEG as the source of affective signal for this project.

Chapter 5: The Brain, EEG & Emotion

“A Window Into The Brain”, Hans Berger

Tiny electrical potentials emanating from the brain’s cerebral cortex when measured from the surface of the scalp can be amplified to produce an Electroencephalogram, or EEG. These electrical potentials, caused by the collective activation of neurons (brain cells) in the underlying brain areas, can be measured unobtrusively from the surface of the scalp using small metal electrodes. The signals are caused by local current flows between neurons, and indicate when mental processing is taking place. The part of the brain that produces the clearest EEG signals lies just below the surface of the scalp and is called the cerebral cortex. This region consists of the right and left hemispheres of the brain and is said to control conscious experience, including perception, thought, planning and most notably the management of emotions. EEG has been found to be a very powerful tool in the field of neurology and cognitive science, due to its capability to show patterns of electrical signals which can then be used to determine and differentiate between different types of brain activity.

Hans Berger measured the first EEG in Germany in 1929 thus earning the recognition of “Father of Electroencephalography”. From seventy-three EEG recordings taken from his son, Klaus, Berger noted that the electrical patterns emitted from his son’s brain could be seen to shift with attention, showing different patterns and frequencies when Klaus was at rest, to when he was at rest but focusing on solving a maths problem. Berger went on to categorise four main frequency bands which could be shown to correlate with different levels of brain activation. These frequency bands are commonly referred to as brain waves. (see Figure 4-4: Brain wave samples indicating the four most dominant frequencies.) These various brain waves can be used as a measure of a

subject's alertness, simply by determining which brainwaves are most dominant within raw EEG data;

- Beta relating to a high level of alertness, involving cognitive processing, reasoning and concentration.
- Alpha relating to calmness, relaxation and creativity.
- Theta relating to near sleep, daydreaming.
- Delta relating to deep dreamless sleep.

These rather crude measures of affective state can already allow us to detect whether a subject is alert, asleep, daydreaming or relaxed. However in order to extract more useful affective information it is important that I first explore the various parts of the brain that are involved in the processing of our emotions. This will allow us to deduce how, and from which parts of the brain, to best measure our affective state.

5.1 How the Brain Processes Emotions

Historically research in the area of the brain and emotion generation was split into two opposing groups. The peripheralists' view postulated the source of our subjective feelings of emotion as simply a reaction to changes in the peripheral nervous system. They believed that we become sad because we started to cry, or that we become scared because we started to shake. This view was countered by the centralists, who argued that the brain is the true source of our emotions which in turn are the cause of the physiological changes evident in our peripheral nervous systems. Recent studies suggest, in a triumph for bipartisan thinking, that they were in fact both correct, supporting the view that, for example, if you smile you generally feel happier, and if you feel happy you generally smile.

Evidence in support of the centralist view was first outlined by (Papez J.W. 1937 [29]) in his work entitled, "A Proposed Mechanism of Emotion" which stated that anatomical structures in the brain must "deal with the various phases of emotional dynamics". His work in attempting to define the structures of the brain that deal with emotions, (which bizarrely involved the injection of rabies into cats, to observe its

progress through the brain), led to his discovery of what is now called the Papez Circuit. Unfortunately for Papez this circuit proved to have little involvement in emotion but did form the basis of the limbic system theory of emotion.

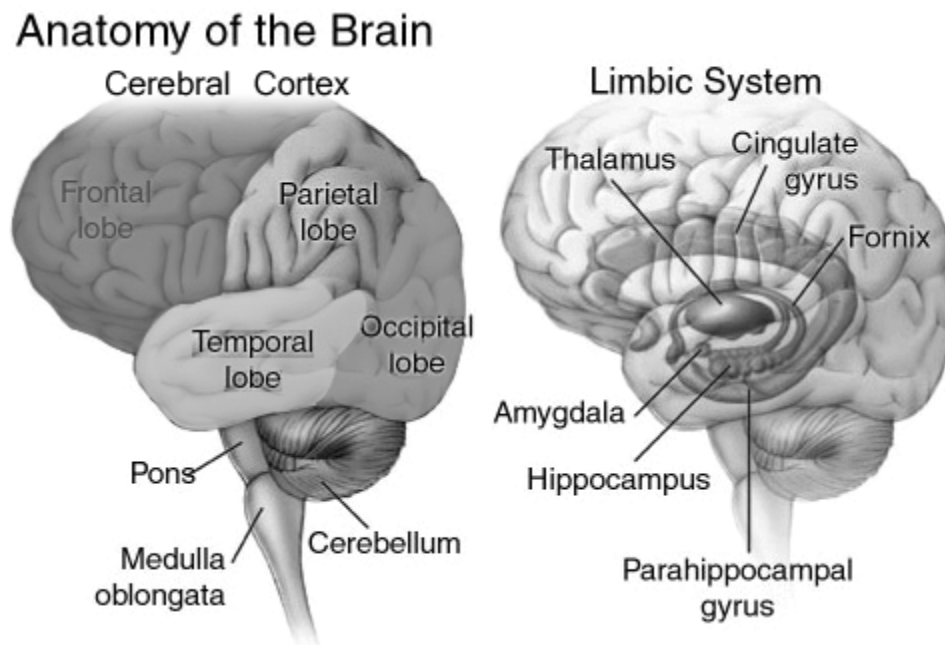

Figure 5-1: (left) Cerebral Cortex, showing the major lobes (frontal, parietal, temporal and occipital) and the brain stem structures (pons, medulla oblongata, and cerebellum). (Right) Limbic System inside the brain. Consists of the fornix, hippocampus, cingulate gyrus, amygdala, parahippocampal gyrus and thalamus.

Dr Paul MacLean, MD, the former director of the Laboratory of the Brain and Behaviour at the US Institute of Mental Health, building upon Papez's work, outlined the importance of the limbic system in emotion processing (P.D MacLean 1949 [37, P.D MacLean 1952 [38]). The Limbic System, also known as the old mammalian brain consists of a number of structures located inside the cerebral cortex, including the fornix, hippocampus, cingulate gyrus, amygdala, parahippocampal gyrus and the thalamus. (See Figure 5-1 above). MacLean went on to develop a model of the brain based on its evolutionary development, known as the Triune Brain (P.D MacLean 1973 [39]). This model consists of three parts, hence the name triune, the limbic system making up the second part. MacLean proposed that the evolution of the human brain could be differentiated into three stages, such that at each stage, new layers of brain developed upon the old ones. In a process similar to

the way that, in object oriented programming, the functionality of one class can be inherited by another in order to adapt to more specialised tasks without losing any of the underlying functionality. In this way MacLean proposed three classes of brain function, each inheriting from the others, to form more complex and intelligent systems.

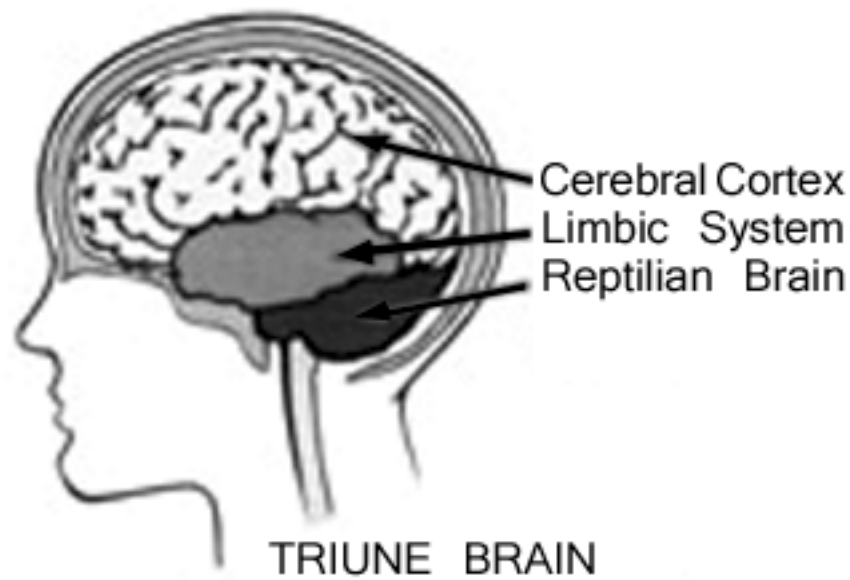

Figure 5-2: MacLean's Triune Brain

The three layers outlined by MacLean are:

The Reptilian Brain (R-Complex) consists of the brainstem and cerebellum and is considered the oldest part of the brain. Similar structures, found to dominate the brains of reptiles, explain the name, but also go to illustrate the types of behaviour governed by this primitive brain, which seem aptly reminiscent of our notions of reptilian behaviour. This part of the brain is described as being obsessive, compulsive, ritualistic and paranoid. It is also evident that the function of this primitive brain is not to learn but to keep repeating the same actions over and over again, as it does to control our respiration, circulation and autonomic functions.

The Limbic System (old mammalian brain), formed in part by the Papez Circuit, is the middle part of the trio and corresponds to the brain of early mammals. It is seen as the source of our basic emotions and instinctive behaviours such as feeding, fleeing, fighting and sexual reproduction. The Limbic System is perhaps the most important component of the brain when it comes to emotion, as it seems to be the

primary seat of our basic emotions and emotion charged memories. MacLean notes that when this part of the brain is stimulated by mild electrical current, emotions such as fear, rage, joy, pleasure and pain are produced. The amygdala, a component of the limbic system is thought to be principally involved in our ability to associate certain events with exacting emotions. Another component the hippocampus, seems concerned with the conversion of experienced events into long-term memories and in the recollection of these memories. Therefore, the limbic system provides the mechanisms which can be used to learn from past experiences, giving rise to emotionally charged memories that illicit feelings such as fear, pity, anger and outrage. Fight or flight reactions, for example, coming from the reptilian brain can also trigger these emotions in the limbic system, this has allowed instinctual behaviour to evolve throughout our development, affording us the best chances for survival.

The limbic system also has vast interconnections with the third part of the brain, the Cerebral Cortex. The Cerebral Cortex (neo-mammalian brain, neocortex) is known as the superior and rational brain. This brain corresponds to those of primates and consequently to the human brain. The cerebral cortex makes up five sixths of the human brain and is what has given us our capacity to exhibit unique abilities such as language, writing, complex logical thought, rationalisation, visualisation, creativity etc. MacLean describes the cerebral cortex as “the mother of invention and the father of abstract thought”.

The cortex is divided into the better known left and right hemispheres, with the left hemisphere, concerned with logical, rational and verbal abilities, controlling the right side of the body, and the right hemisphere, concerned with spatial, artistic, musical and abstract abilities, controlling the left side of the body.

As far as our basic emotions are concerned, the cortex is where we learn to control them, and try, on some occasions to suppress them. MacLean considers the pre-frontal cortex as the essential area concerned with the control and conscious management of our emotional reactions. This area also allows us to plan and even anticipate our own emotions, giving our rational brain the chance to step in, with our pre-conceived checklist of cultural rules, as it were, before we find ourselves reacting directly to the powerful basic emotions emanating from our more primal brains. The

importance of the pre-frontal cortex in emotion processing is strongly supported by several studies, using EEG, MEG, PET and fMRI brain imaging techniques,(R.J. Blair, et al. 1999 [3, R.J. Davidson 1992 [17]), (M. L Phillips, et al. 1997 [44]) among many others. Many of these studies concentrate on collecting evidence in support of several hypotheses, which generally relate to the lateralisation of emotions².

5.2 The Lateralisation of Emotion

In section 3.2 Models of emotion, I concluded that Wundt's 2D valence/activation space as a fitting model of human emotion, however there are other models of emotion that relate directly to the processing of emotions in the brain which must also be examined, in order to attempt the extraction of affective information from EEG data. The majority of these models examine the function of the frontal lobes in the emotion processing and deal with the concept of hemispheric specialisation, or the lateralisation of emotion. Two such hypotheses are the Right Hemispheric hypothesis and the Valence hypothesis, both of which I will now examine.

5.2.1 Right Hemisphere hypothesis vs The Valence Hypothesis

The right hemisphere hypothesis (RHH) seeks to prove the dominance of the right hemisphere over the left for the processing of all forms of emotion expression and perception. The valence hypothesis on the other hand, states that the right hemisphere is only dominant for negatively valenced emotions, while the left hemisphere is dominant for the expression and perception of positive emotions. Both hypotheses are supported by empirical evidence however neither has achieved prominence. In fact some new studies using brain imaging techniques suggest that both hemispheres are used in the processing of positive and negative emotions, the right hemisphere exhibiting dominance only to certain stimuli.

² lateralization of emotions - the act of using one hemisphere more than another in the processing of emotions.

Evidence in support of the RHH first came from brain lesion studies carried out by Jules Bernard Luys in 1881. He recognised that patients suffering from damage to their right hemisphere, as a result of stroke or some other causes, which I generally describe as brain lesions, exhibited only passive and indifferent behaviour acting entirely without affect, whereas patients suffering with lesions on the left hemisphere were described as emotionally volatile. Luys believed that this was a result of damage to the normal emotion inhibiting centres of the brain, which he postulated must then reside in the right hemisphere of the cortex. Behavioural evidence also lends its support to the RHH. The left side of the face, for instance, is more comprehensive and communicative in facial expressions, the muscles of which are controlled by the right hemisphere of the brain (H.A. Sackheim and R.C. Gur 1978 [49]) . It can also be shown that the right hemisphere is also better at perceiving emotion than the left hemisphere. Evidence for this comes again from lesion studies, where patients with right hemisphere injury exhibit greater difficulty recognising positive and negative emotions in faces than those with left hemisphere injuries (D. Bowers, et al. 1985 [6]).

Contrary to this, evidence in support of the valence hypothesis (VH) seems also to be readily available. It must be said that more of this evidence comes from brain imaging techniques such as EEG, PET and fMRI and less from brain lesion studies than it does in support of the RHH. (R.J. Davidson, et al. 1979 [18]) show empirical evidence, taken from EEG studies of adults and infants, that the left frontal region of the brain is involved in the experience of positively valenced emotions, the right frontal region being involved with negatively valenced emotions. This evidence is also supported by (N.A. Jones and N.A Fox 1992 [30]), who show greater left frontal EEG activity associated with the viewing of film clips showing pleasant scenes and greater relative right frontal EEG activity associated with the viewing of unpleasant film excerpts. (L.A. Schmidt and L.J. Trainor 2001 [50]) noted similar results using musical excerpts to illicit positively and negatively valenced emotions across the left and right frontal regions respectively.

More importantly for this study (L.A. Schmidt and L.J. Trainor 2001 [50]) studies show that the pattern of frontal brain activity reflects both the valence and intensity of emotions. This proves that by examining both asymmetry and overall power of frontal brain activity it is possible to distinguish between emotions within the

valence/activation model using EEG data alone. This adds final justification for the conclusion drawn in section 4.4 to base the affective choice interface system exclusively on EEG measurement of affective signals.

5.3 The recording of EEG

Now that I have demonstrated that it is possible to derive a user's affective state from their EEG signals alone, it is important that I outline further the process of EEG acquisition.

EEGs are differential amplifiers. They take measurements of electrical potentials emanating from the brain, between two points on the scalp using metal electrodes and conductive gel, amplifying the difference between these measurements. All EEG amplifiers therefore require at least two electrodes, generally referred to as the active and reference electrode. In any practical amplifier a ground electrode is also required, this electrode does not need to be connected to the scalp and is often connected to the ear lobe, or mastoid. It is used to record noise which can then be identified in the active and reference signals for removal. When taking measurements from more than one channel (area of the brain) two electrodes per channel are required, in addition to the ground electrode. The EEG Amplifier used in the development of this affective interface, provides just two channels.

Sources of noise in EEG recording most often result from; body movements that result in the connected wires being pulled, resulting in the disruption of the electrodes, muscle movements including minor movements such as eye blinks and eye movements, and changes in the quality of scalp connection due to using too much conductive gel, gel drying out or the subject sweating.

5.3.1 Types of electrode

The most common types of electrodes used include; disposable gel electrodes, reusable disk electrodes (gold, silver, stainless steel or tin), electrode caps and saline-based electrodes. In the development of the affective interface, simple disk electrodes in combination with Ten20 conductive gel were used. These electrodes simply stick

to the surface of the scalp, by the application of a small amount of conductive gel. The actual metal part of the electrode is not in contact with the scalp; instead the conductive gel between the two makes the connection.

Alternative sensors available include flextrodes. These flextrodes are saline-based electrodes which allow for better connection through the hair and provide a more attractive alternative to gels and pastes. For the purposes of affective measurement using EEG, the use of flextrodes in combination with either headbands or electrode caps would provide a more practical wearable interface than using disk electrodes with conductive paste. If this type of interface proves popular one can imagine the design of EEG sensors going along the lines of audio headphones, or some more adventurous sunglass designs. These more fashionable designs would still incorporate the some basic flextrode design.

5.3.2 Electrode placement

With the increased research and use of EEG devices, a standard description for electrode placement was developed by the International Federation in Electroencephalography and Clinical Neurophysiology in 1958. This is known as the 10-20 electrode placement system. The name comes from the suggested arrangement of electrodes in relation to areas of the scalp at intervals of 10 or 20 percent of the proportional distance from easily recognisable landmarks such as the ears and nose.

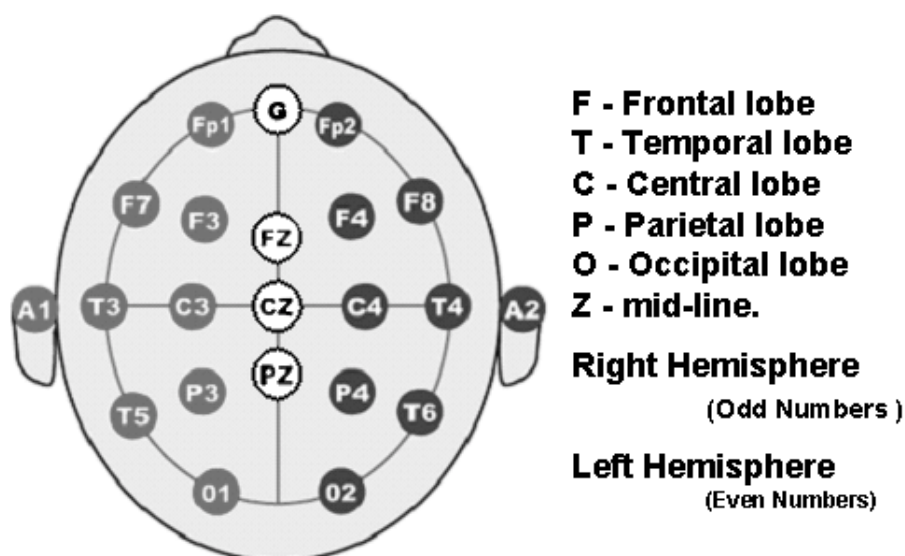

Figure 5-3: 10-20 Electrode Placement System

5.4 Conclusion

In this chapter I have examined the relevant areas of emotion processing in the brain. I presented information regarding the recording of EEG signals from the brain including the choice of various electrodes and the 10-20 electrode placement system. I examined MacLean's Triune model of the Brain, based on its evolutionary development (P.D MacLean 1973 [39]) and the role of the various parts of the brain in the generation, processing, memory and management of emotions. Most importantly, however, I have demonstrated that it is possible to derive a user's affective state from the recording and inspection of their EEG signals alone. This pivotal piece of evidence allows me to now tie together all the research presented regarding the valence/activation model of emotion, the choice of EEG and the measurement of EEG signals from the pre-frontal cortex of the brain and to finally outline the best design for the affective choice interface system.

Chapter 6: The Affective Interface System

The Affective Choice system is an affective computing user interface. It uses affective signals derived from the emotion centres of the user's brain and applies these signals to a support vector machine (type of neural net) which learns to classify these signals into various emotion states. This system is designed to provide application developers with an easy to implement affective user interface which will afford their systems an affective sense of their user's emotional state, which can be exploited to provide unique services to the user based entirely on their mood. The system can detect and describe a user's affective patterns (emotional cues), and learn to equate these emotional patterns with the user's desired actions (within an application) through a reinforcement-learning framework.

6.1 Overview of the Affective Interface System

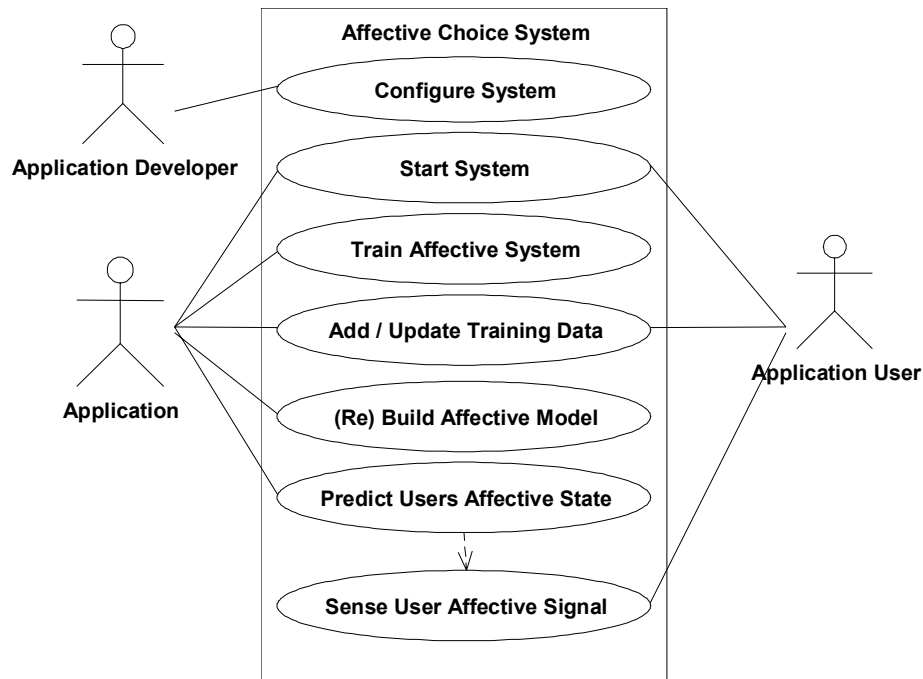

Figure 6-1: Use Case Diagram of Affective Choice System

The affective interface system consists of two main components, the Brainmaster EEG sensor and data acquisition module, and the Support Vector Machine, used for classification and regression of EEG data. Both these components are brought together to make up the affective choice system, which is largely a prototype application programming interface. Written in C and C++, this “Affective API” provides a high level object oriented interface, controlling the retrieval and processing of EEG data, along with training and learning mechanisms used in the classification of this EEG data into various forms of affective signals. The most important work in the design of this system has already been outlined in the preceding chapters, and largely involves the careful research and examination that was pivotal to the choice of the correct components for the system. With these in place, the next challenge would include the design of a reusable, easy to understand and implement interface, suitable for use in future ubiquitous applications and not least to demonstrate that the final system could in fact fulfil its objectives, as a affective user interface, and therefore justify its reuse.

The final design of the affective interface system will now be outlined, along with descriptions of its various components and classes.

6.2 System Components

6.2.1 Brainmaster Module

The Brainmaster Module is a portable, battery powered EEG monitor. It is designed and marketed for use in the area of clinical psychophysiology³ and neurofeedback, a technique used, for instance, in the treatment of epilepsy, attention deficit disorder and rehabilitation of traumatic brain injury among others. The Brainmaster unit consists of two EEG amplifiers, an analogue to digital converter and a sensor fusion system. The module automatically applies digital filters, coherence processing and Fast Fourier Transform (FFT) processing to the raw EEG signal, and provides

³ Physiological Psychology or Psychophysiology: is the branch of psychology that is concerned with the physiological bases of psychological processes.

constantly updated and frequency resolved EEG data on the fly. The module also applies various noise and artefact detection and reduction techniques. The successive approximation digitiser runs at 120 samples per second, this can be boosted to 244-800 samples per second if time critical measurements are required, the default 120samples/sec was used for the duration of development and testing. Conversion time of 16msec is exhibited in both channels, with eight-bit precision and an accuracy rating of half the least significant bit. The EEG module automatically resolves raw EEG in to the following frequency ranges:

One Nominal Range	-	User Adjusted
Delta	-	1-3 Hz
Theta	-	4-7 Hz
Alpha	-	8-12 Hz
Lo-Beta	-	12-15 Hz
Beta	-	15-20 Hz
Hi-Beta	-	20-28 Hz
Gamma	-	28-42 Hz

EEG frequencies are measured using a number of techniques by the Brainmaster module. One technique uses Fast Fourier Transform (FFT) which estimates the amount of energy emitted over a user selectable time period (usually about one second). This technique provides greater accuracy, but lacks a fast response. The other technique applies software digital filters, this provides a faster response, and readings are separated into their specific bands. Samples taken using this technique gave preferred higher resolution measurements which proved more useful for this application.(Ph.D Thomas F. Collura December 7, 1997 [52])

Figure 6-2: Picture of the Brainmaster EEG Module used in the development of the Affective Choice system, (Thomas F. Collura [12])

The Brainmaster EEG module was provided to us by Thomas F. Collura of BrainMasterTechnologies,Inc. (Thomas F. Collura BrainMasterTechnologies,Inc. [11])

6.2.2 Support Vector Machine for Classification and Regression

Support Vector Machine (SVM) provides a technique for data classification, often used in areas such as bioinformatics, and astro particle grouping studies. Support Vector Machines are learning machines designed to perform pattern recognition and function approximation or regression estimation tasks. SVMs provide the ability to map non-linear input from a multi-dimensional space into a multi-dimensional feature space. From this feature space a linear classifier or classification model is constructed. SVMs were chosen for this project because they are seen to be more easily understood than Neural Networks and therefore they provide a platform for data categorisation which can be more easily adopted and used by application developers. This is in line with the goals of this project, to provide a reusable, easy to implement and understand, affective user interface for developers of ubiquitous computing applications.

Figure 6-3: Graphical Depiction of how SVM learns to classify or group reading into categories. (LEFT) This depicts a 2D set of training data, containing 3 distinct categories. (RIGHT) Depicts the SVM attempt to build a classification model for this distribution. This Model can then be used to determine the category of any future readings.

As depicted in Figure 6-3, the SVM uses a set of labelled training data, this training data is arranged in a training file (text file) in LIBSVM format as outlined below. Each line in the training file (training vector) contains one “target value” (Label) and

several “attributes” (feature values or dimensions). The goal of SVM is to produce a multi-dimensional model, which predicts the target value of real-time data instance attributes accurately.

```
<Label> 1:<1st Attribute Val> 2:<2nd Att Value> ..... N:<Nth Att Val>
<Label> 1:<1st Attribute Val> 2:<2nd Att Value> ..... N:<Nth Att Val>
<Label> 1:<1st Attribute Val> 2:<2nd Att Value> ..... N:<Nth Att Val>
```

Figure 6-4: LIBSVM vector data format

As outlined in (Chih-Wei Hsu, et al. [26]) & (B. Boser, et al. 1992 [5]) support vector machines (SVM) require the solution of the following optimisation problem:

$$\begin{aligned} \min_{w,b,\xi} \quad & \frac{1}{2} w^T w + C \sum_{i=1}^l \xi_i \\ \text{subject to} \quad & y_i(w^T \phi(x_i) + b) \geq 1 - \xi_i, \\ & \xi_i \geq 0. \end{aligned}$$

Training vectors (lines of training file), denoted (x_i) above, are mapped by the function ϕ into higher and higher (maybe infinite) dimensional spaces. The SVM finds separating boundaries within these multi-dimensional spaces. Parameter C is the penalty parameter of the error term. A large penalty parameter gives a more precise model based on the training data, however this is not always desirable, as the models become less predictive and very specific. A penalty parameter of 1 was used for general purposes.

There are various kernels to choose from, some linear and some nonlinear. These kernels are used to map samples into the higher dimensional spaces. The choice of kernel has a large impact on the performance of the SVM. The best kernel for general application is the RBF kernel, as it is a non-linear kernel (it can handle the case when the relationship between labels and attributes is nonlinear), and it exhibits the best results for general classification purposes(Chih-Wei Hsu, et al. [26]).

There are four basic kernels to choose from:

$$\begin{aligned} \text{Linear:} \quad & K(x_i, x_j) = x_i^T x_j. \\ \text{Polynomial:} \quad & K(x_i, x_j) = (\gamma x_i^T x_j + r)^d, \gamma > 0. \end{aligned}$$

Radial Basis Function (RBF): $K(x_i, x_j) = \exp(-\gamma \|x_i - x_j\|^2), \gamma > 0.$

Sigmoid: $K(x_i, x_j) = \tanh(\gamma x_i^T x_j + r).$

The LIBSVM C++ Library for Support Vector Machines provided the base class for the implementation of SVMs in this thesis.

6.3 System Architecture

As shown in Figure 6-5, the Affective Choice Interface consists of 6 classes. AffectiveInterface, BrainmasterInterface, SVMInterface, SVMPredictor, SVMScaler and SVMTrainer. The BrainmasterInterface class is a singleton interface for the setup and retrieval of data from the Brainmaster EEG module. Data retrieved from the Brainmaster EEG module is sent to the SVMInterface which consists of three main classes (see below). The SVMPredictor, is used along with the SVMScaler class to scale and classify the user's affective data coming from the BrainmasterInterface, according to an n-dimensional, multi attribute model of the user's EEG signals.

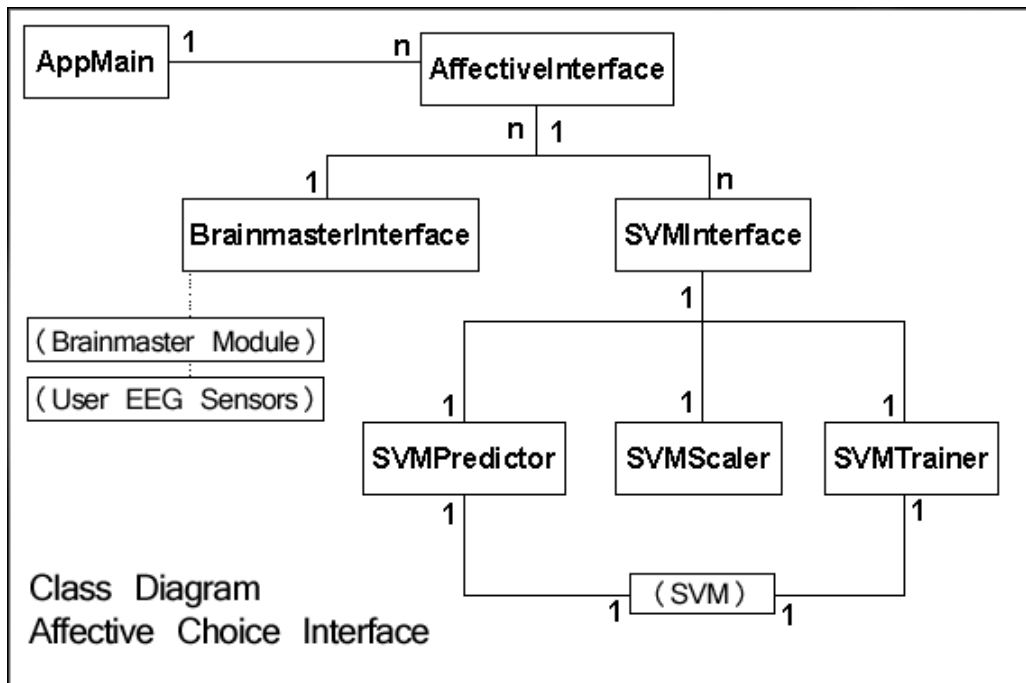

Figure 6-5: Shows Class Diagram of Affective Interface System, including (system components), Brainmaster EEG Module, and LIBSVM base class.

The result of this classification indicates the predicted affective state (mood, emotion) of the user based on their current EEG signals, and is derived from the previously created SVM classification model of the user's possible affective states. This allows an application using the interface to simply call the getCategoryPrediction() method of the AffectiveInterface class, and the system will quickly return the predicted affective state of the user, 1:angry, 2:calm, 3:focused etc.

The SVMTrainer is used along with the SVMScaler class in the recording of training data from the user and in the creation and update of the SVM model of that user's affective signals. For instance, a happy/sad model can be created by calling the writeNewTrainingFileData() method specifying the number of samples to take and the type of EEG signal to build the model from (e.g. alpha, beta, lobeta), when the user is feeling happy. Later when the user is feeling sad, a number of samples using the same criteria are appended to the training file by calling the appendToTrainingFileData() method of the AffectiveInterface. A new model for happy/sad can now be created using a simple call to the createNewModel() method, this scales the training data and applies the SVM classifier to the data. The SVM classifier searches out any patterns or groups within the n-dimensional training set and produces a model of the attributes of the user's EEG signals when they are happy, as opposed to when they are sad.

This model can then be applied to real-time data, using the prediction mechanism, to let an application know whether the user is happy or sad, based on their affective signals.

6.4 Overview of the Brainmaster Interface

The BrainmasterInterface singleton class provides a simple interface for the setup and retrieval of data from the Brainmaster EEG module. Control and retrieval from the BrainMaster is achieved by reading and writing to memory locations within the BrainMaster module's dll memory space. The dll extension library header file (see Appendix: Source Code), provided with the module, defines all the data offsets into the BrainMaster dll memory space.

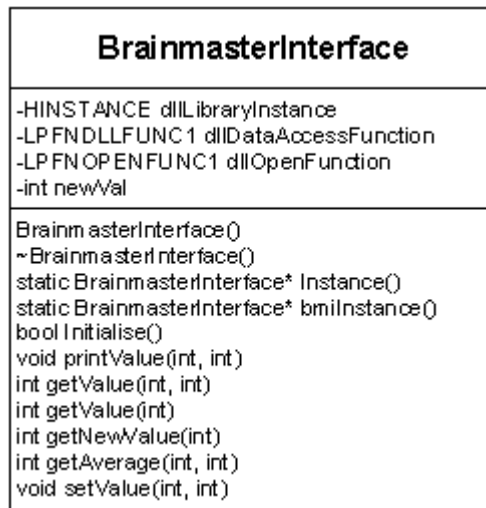

Figure 6-6: BrainmasterInterface Class Diagram

This class includes code to access data in the BrainMaster 32bit Dll. Once connected and logged into the BrainMaster module the class exposes 5 main methods:

`printValue(memorySpaceBlock, offset)` – prints EEG value at memory location `memorySpaceBlock+offset` in the BrainMaster dll memory space to std out.

`getValue(memorySpaceBlock, offset)` – returns integer EEG value at memory location `memorySpaceBlock+offset` in the BrainMaster dll memory space.

`getNewValue(memorySpaceBlock+offset)` – returns the next EEG reading, blocks until new reading is written to the dll memory space. `memorySpaceBlock+offset` is passed in to identify parameter to be read.

`getAverageValue(memorySpaceBlock+offset, numSamplesToAverage)` – returns the average of a specified number of new EEG samples. Useful to ensure more accurate readings and reduce signal artifacts.

`setValue(memorySpaceBlock, offset)` – is used to write configuration information to the BrainMaster dll memory space control block, in order to configure the EEG module.

All block and offsets into BrainMaster dll memory space are #defined in `Dlldefs.h`, see Appendix: Source Code for details.

6.5 Overview of SVM Machine Learning Interface

The SVMInterface class provides a high level interface for the easy control and use of the LIBSVM library (Chih-Chung Chang and Chih-Jen Lin 2001 [9]). The SVMInterface class is designed to be used by application developers who need not have any experience using an SVM. It includes a default setup configuration that is tailored for general application, and will provide good classification for most implementation purposes. It still, however, allows more experienced developers to configure the SVM exactly as they please.

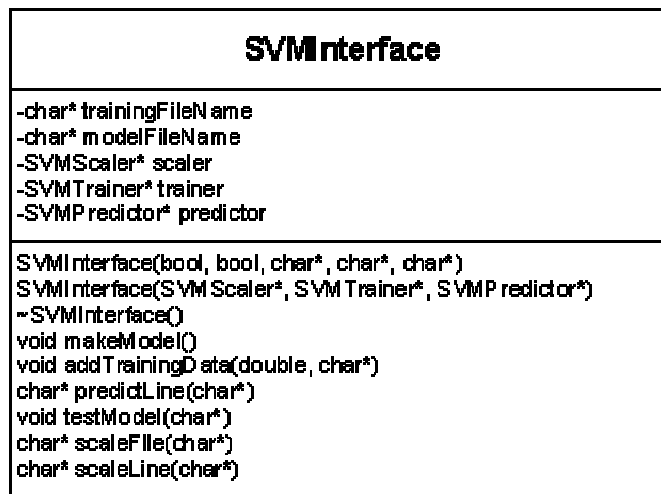

Figure 6-7: SVMInterface Class Diagram

The SVMInterface has two constructors. The first provides default values for most of the parameters required for SVM classification. The only parameters needed are:

- `bool produceNewScale`: If true, a new SVMScaler is created with its default configuration. This configuration is then saved for future use to `scaleConfigFile`. If false, an instance of SVMScaler is recreated using the data saved in `scaleConfigFile`.
- `bool produceNewModel`: If true, a new model is created by using the training data and new SVMScaler configuration. This model is then saved for future use to `modelFileName`. If false, a previously existing model is recreated using the data saved in `modelFileName`.
- `char* scaleConfigFile`: Path and filename of scalers save/restore config file
- `char* trainingFileName`: Path and filename of training file (LIBSVM format)
- `char* modelFileName`: Path and filename of model file

The second constructor requires that the user explicitly creates an instance of each of SVMScaler, SVMTrainer and SVMPredictor, and these are passed as parameters to the constructor.

SVMInterface allows complete control of the underlying SVM classes, SVMScaler, SVMTrainer and SVMPredictor through the following five methods:

makeModel() – produces a new model from the supplied/updated trainingDataFile.

addTrainingData(value, inputLine) – appends training data to training data set, this should be done when the predictor gets a value wrong. This allows the system to learn from its mistakes.

predictLine(inputLine) – predicts category classification of data provided in inputLine.

testModel(testFileName) – tests the model by predicting values from testFileName and comparing them to the desired 'target' values.

scaleFile(trainingFileName) – used to rescale trainingFileName when needed.

scaleLine(line) – scales the line according to SVMInterface scaling configuration.

6.5.1 SVMInterface Component Classes

The three component classes of the SVMInterface themselves provide abstraction to the LIBSVM system under the categories of scaling, training and prediction. Each of these three component classes will now be outlined.

6.5.2 SVMScaler

SVMScaler is used to scale all training and input data before it's used either to create a model or used with SVMPredictor. It is advised to use scaling in all SVM systems in order to avoid attributes in greater numerical ranges dominating those in smaller numerical ranges. Another advantage is to avoid numerical difficulties during the

calculation. The use of smaller number ranges also improves efficiency in classification.

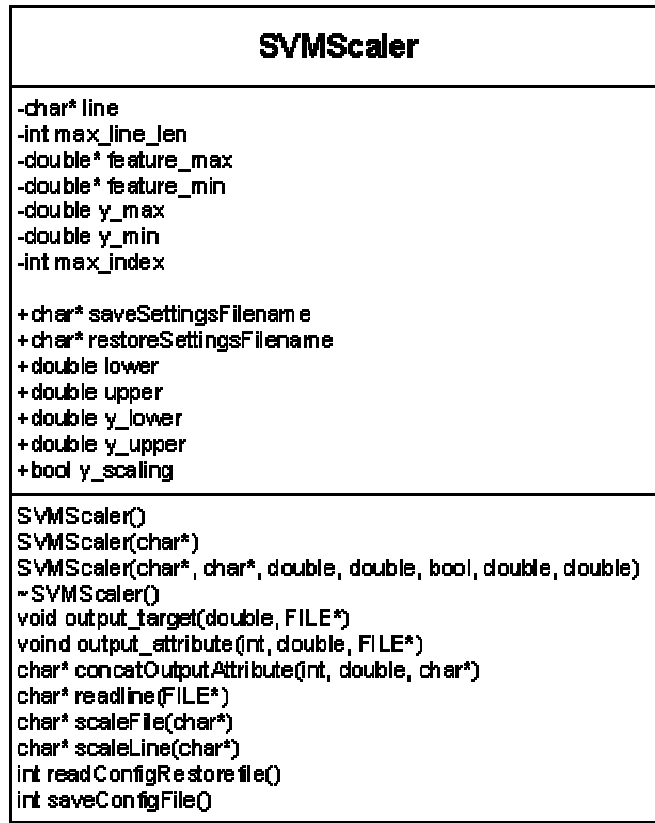

Figure 6-8: SVMScaler Class Diagram

SVMScaler has three constructors. The first constructor is a default constructor. The second constructor requires the path to the scaler configuration file, which is used to recreate a previously existing instance of an SVMScaler. The third constructor allows experienced developers to specify unique configuration of the scaler parameters.

These parameters include:

- char* saveSettingsFilename: Path & filename of scaler config save file
- char* restoreSettingsFilename: Path & filename of scaler config restore file
(usually the same)
- double lowerBound: Lower x bound (usually -1)
- double upperBound: Upper x bound (usually 1)
- bool yScaling: Whether y scaling is to be used
- double y_lowerBound: Lower y bound
- double y_upperBound: Upper y bound

‘x’ and ‘y’ in the above specification refer to the sampled attribute values and classification labels of each line or training vector. (See Figure 6-4)

6.5.3 SVMTrainer

SVMTrainer is used expressly for the creation of classification models. It is the most important of the three component classes and due to this it is also the most complex to initialise. In order to initialise SVMTrainer it is necessary to first decide how you wish to apply the Support Vector Machine. Once the SVMTrainer has been initialised, and the model produced, all configuration data is recorded as part of the model file which allows for easy re-creation of previous implementations of the SVMTrainer.

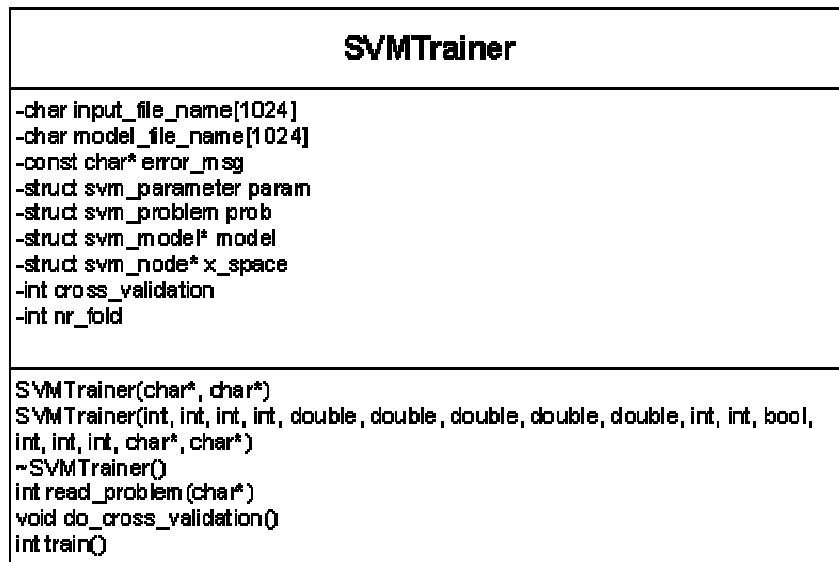

Figure 6-9: SVMTrainer Class Diagram

SVMTrainer has two constructors. The first allows for easy re-implementation of a previously created model and requires only pointers to the training data file name and the previous model file name and uses general default values optimised for use with generalised classification problems. The second constructor is used in the construction of new implementations of the Support Vector Machine. In order to call this constructor it is necessary that we pass in all the variables required and used by structures within the LIBSVM base class (For implementation details see (Chih-Wei Hsu, et al. [26])). These parameters are outlined below:

- svm_type : Set type of SVM (default 0)
 - 0 -- C-SVC
 - 1 -- nu-SVC
 - 2 -- one-class SVM
 - 3 -- epsilon-SVR
 - 4 -- nu-SVR
- kernel_type : Set type of kernel function (default 2)
 - 0 -- linear: $u \cdot v$
 - 1 -- polynomial: $(\gamma \cdot u \cdot v + \text{coef0})^{\text{degree}}$
 - 2 -- radial basis function: $\exp(-\gamma \cdot |u-v|^2)$
 - 3 -- sigmoid: $\tanh(\gamma \cdot u \cdot v + \text{coef0})$
 - 4 -- precomputed kernel (kernel values in training_set_file)
- kernelFuncDegree : Set degree in kernel function (default 3)
- kernelFuncGamma : Set gamma in kernel function (default 1/k)
- kernelFuncCoef0 : Set coef0 in kernel function (default 0)
- KernelFunctNU : Set the parameter nu of nu-SVC, one-class SVM, and nu-SVR (default 0.5)
- cacheSizeMB : Set cache memory size in MB (default 100)
- svmCostVal : Set the parameter C of C-SVC, epsilon-SVR, and nu-SVR (default 1)
- epsilonTerminationCriterion : Set tolerance of termination criterion (default 0.001)
- epsilonSVR_EPS_Val : Set the epsilon in loss function of epsilon-SVR (default 0.1)
- shrinking: Whether to use the shrinking heuristics, 0 or 1 (default 1)
- probabilityEst: Whether to train a SVC or SVR model for probability estimates, 0 or 1 (default 0)
- wi weight: Set the parameter C of class i to $\text{weight} \cdot C$, for C-SVC (default 1)
- crossValidation: Whether to use n-fold cross validation
 - numFold: n-fold cross validation mode
- C_SVCClass: Set the parameter C of class <C_SVCClass> to $\text{weight} \cdot C$, for C-SVC
 - weight: (default 1)
- input_file_name: Path & filename of file containing training data
- model_file_name: Path & filename of model file

6.5.4 SVMPredictor

SVMPredictor is used to make classification predictions based on attribute line inputs (vectors). It consists of two prediction methods. The most commonly used of these is the predictLine() method which performs model categorisations based on vector line inputs. The second method, testPredictFromFile(), is used expressly for testing purposes. This method takes an input file name and output file name as parameters. The input file contains test data in LIBSVM format. Predictions are

made based on the vector attributes of each line within the file, and compared to the test categories (labels) assigned to each line. Predicted categories are written to the output file and statistics outlining the how well the model performed are printed to stdout for evaluation.

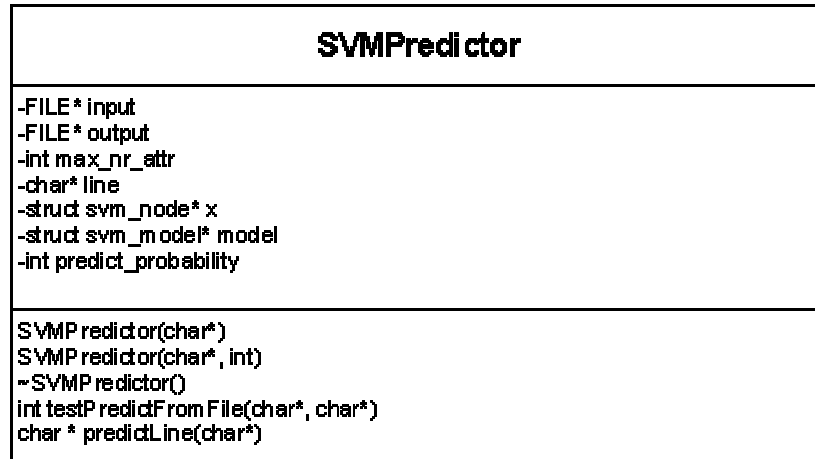

Figure 6-10: SVMpredictor Class Diagram

SVMpredictor contains two constructors. The first takes as parameter the model file name, and the second takes this along with the option of using probability estimates⁴ with the model.

6.6 Overview of AffectiveInterface

As seen in Figure 6-5 the AffectiveInterface class acts as a façade for the entire affective user interface system and allows high level control of the underlying components. These high level methods provide a high level of abstraction allowing developers with only a rudimentary knowledge of the Affective Interface to successfully implement and use the system. Methods such as writeNewTrainingFileData(), appendToTrainingFileData(), createModel() and makePrediction() are all that are needed to operate and benefit from the Affective Choice System. I will now outline the class attributes and methods of the AffectiveInterface.

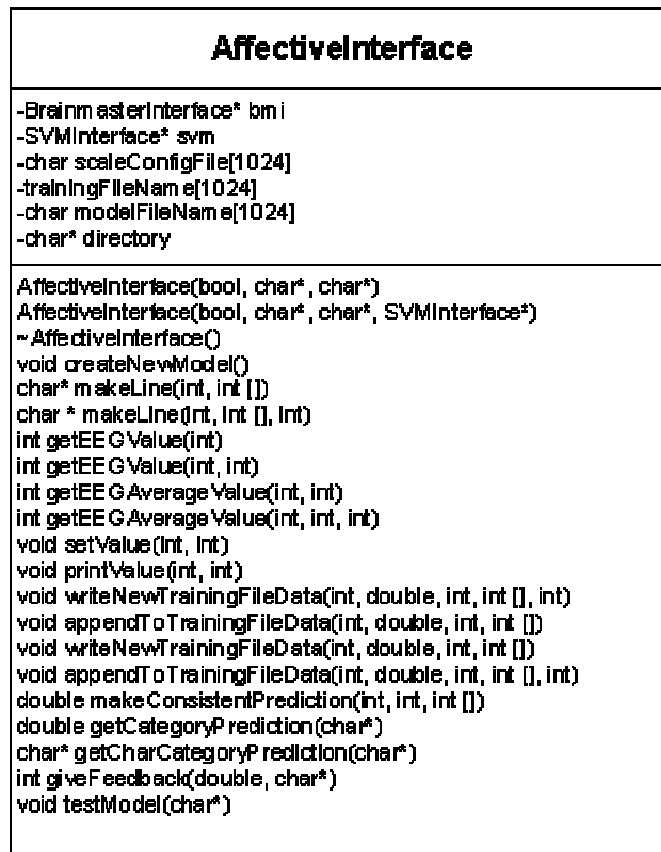

Figure 6-11: AffectiveInterface Class Diagram

The AffectiveInterface class provides two constructors. The first constructor requires the following parameters:

- **bool** produceNewTrainingSet: Set to true if you wish to produce a new training set. Set to false if you wish to reuse and existing training set (training files already exist)
- **char *** dataDirectory: Path to data directory where training files are stored (all training files must be present and in the correct format in this directory, these files include the <trainingDataFile>, the <trainingDataFile>.scaleConfig and the <trainingDataFile>.model)
- **char *** trainingDataFileName: Filename of training file in (LIBSVM format) in directory (filenames for scaleConfig file and model file are derived from this trainingDataFileName by appending “.scaleConfig” or “.model” to it)

The second also requires a SVMInterface pointer, as well as those outlined above.

⁴ For a classification model with probability information, this function gives probability estimates. The class with the highest probability is returned..

The AffectiveInterface class also provides the following methods:

createNewModel() – creates a new classification model from trainingDataFile (LIBSVM format)

makeLine(int, int []) - makes a line (vector) from live EEG Data in (LIBSVM format) to be used in the creation of a training file or category prediction. Parameters include: number of attributes you wish to include on a line and an integer array containing the blockPlusOffset values for each of the EEG attribute readings(see Appendix: Source Code)

makeLine(int, int [], int) – Same as previous method, but here the number of EEG samples you wish to be averaged to make up each line vector value is also specified.

getEEGValue(int) – reads EEG value from block+offset in Brainmaster Dll memory

getEEGValue(int, int) - reads EEG value from block, offset in Brainmaster Dll memory

getEEGAverageValue(int, int) - reads average of numSamples of EEG values from block+offset in Brainmaster Dll memory

getEEGAverageValue(int, int, int) - reads average of numSamples of EEG values from block, offset in Brainmaster Dll memory

setValue(int, int) – used to set control parameter within the Brainmaster Dll memory space as the location specified in the block & offset values.

printValue(int, int) - prints EEG value from block, offset in Brainmaster Dll memory to stdout

writeNewTrainingFileData(int, double, int, int []) – writes training data to a new training file. Parameters include: the number of lines (vectors) to write, the target value (Label) for the readings, number of attributes you wish to include on a line and an integer array containing the blockPlusOffset values for each of the EEG attribute readings(see Appendix: Source Code)

appendToTrainingFileData(int, double, int, int []) – appends training data to a new training file. Parameters include: the number of lines (vectors) to write, the target value (Label) for the readings, number of attributes you wish to include on a line and an integer array containing the blockPlusOffset values for each of the EEG attribute readings(see Appendix: Source Code)

`writeNewTrainingFileData(int, double, int, int [], int)` – as above but also specifies the number of EEG samples to average for each vector value reading.

`appendToTrainingFileData(int, double, int, int [], int)` – as above but also specifies the number of EEG samples to average for each vector value reading.

`makeConsistentPrediction(int, int, int [])` – makes a classification for a consistent prediction for a line using SVM. Method blocks until a certain number of consistent target values are predicted, user is definitely and consistently in that state. Parameters include: number of consistent predictions in a row, number of attributes you wish to include on a line and an integer array containing the blockPlusOffset values for each of the EEG attribute readings(see Appendix: Source Code)

`getCategoryPrediction(char*)` – makes a classification prediction for a line using SVM. Attributes input data line (vector) containing attributes in LIBSVM format

`getCharCategoryPrediction(char*)` – makes a classification prediction for a line using SVM. Attributes input data line (vector) containing attributes in LIBSVM format, returns string representation of double target

`giveFeedback(double, char*)` – appends training data to training data set, should be done predictor gets a value wrong. allows system to learn from its mistakes. Attributes include target, and vector line.

`testModel(char*)` - tests model by predicting values from 'testFileName' and comparing them to the desired 'target' values. Parameter, name of test file(must be in <directory>)

6.7 Using the Affective Interface System

In order to use the Affective Interface System a number of decisions first need to be made. What affective information do you wish from the user, emotion, concentration, valence or arousal? What EEG signal provides the best measure of this affective information, alpha, beta, left to right hemisphere coherence, FFT Lobeta, etc? (See Chapter 5: The Brain, EEG & Emotion p34) Once you know this you must then examine the optimum EEG electrode placement for the reading of these signals, bearing in mind the underlying areas of the brain and the activities they are involved in. These placements are specified using the 10-20 electrode placement system discussed in section 5.3.2 p42.

All of these considerations are very important, and can mean the difference between the interface performing correctly or simply not performing at all. From the discussion in Chapter 5: The Brain, EEG & Emotion I presented the work of (L.A. Schmidt and L.J. Trainor 2001 [50]) as proof that the pattern of frontal brain asymmetry and overall power can be used to distinguish between emotions within the valence/activation model using EEG data alone. From this I was able to define an effective set of EEG electrode placements (Fp1, P3)(Fp2, P4)(Cz)(shown in Figure 6-12). Signals from this arrangement of electrodes when recorded and modelled using the affective interface system, could be shown, in third party demonstrations, to provide both accurate affective information in the activation domain, (relaxed/active) but also in the emotional valence domain (happy/sad). This was the breakthrough that confirmed the usefulness of EEG as a source of affective information, and provided justification for the choice of EEG modelling as the mechanism for the derivation of a subjects emotional state, made in this thesis.

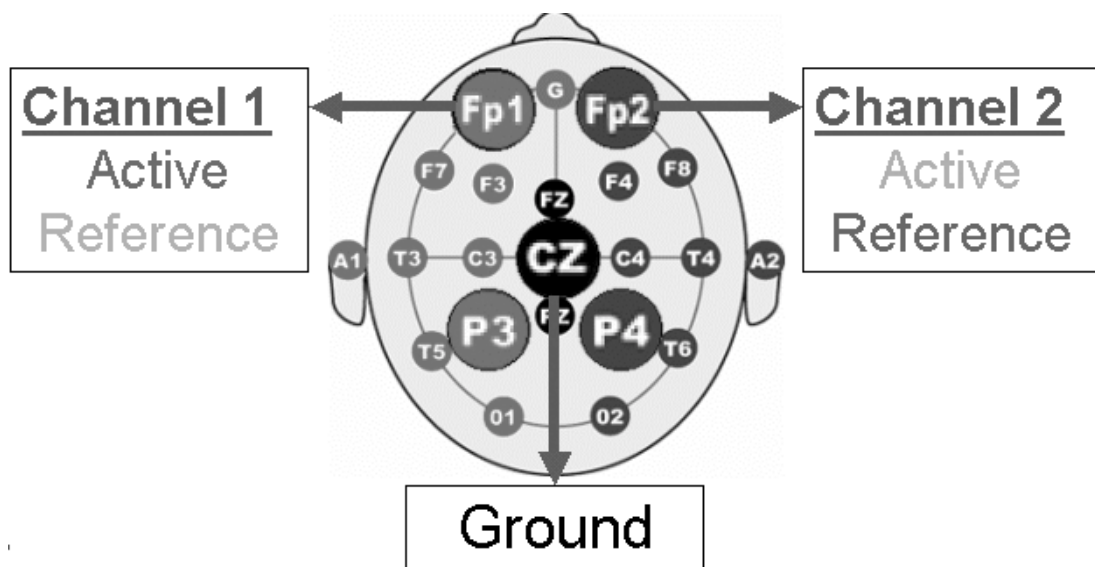

Figure 6-12 : Effective EEG Sensor Placements

Once the type and source of EEG signals are decided upon it is possible to start building a set of training data. This training data will then be used to construct a model for the classification of future affective signals.

Using the writeNewTrainingFileData() method of the AffectiveInterface, a specified number of lines of raw training data can be measured from a subjects EEG signals.

The first set of samples would be taken when the subject is experiencing “type one” emotion (labelled 1 for example). The second, third, ... set of samples would be appended to the training file using the `appendToTrainingFileData()` method, and taken when subject is experiencing “type two/three” emotion and given another label (e.g. 0 or 2). Any number of distinct emotions can be recorded in this way. When this process recording training data has been completed, this data is scaled, generally from -1 to 1 as shown below.

Figure 6-13: 2D training file data showing labels and sample values, this data is then shown scaled from -1 to 1 .

This leaves a scaled set of affective EEG data samples each labelled with the subjects corresponding subjective emotion. When the SVM is then applied to the training data a model of the user’s affective EEG signals is produced. This is achieved by calling the `createNewModel()` method. This model can then be used to categorise affective signals coming from the user into the various labels (0,1,...) therefore identifying what emotion the user is exhibiting. This is achieved by simply calling one of the `getPrediction()` methods of the `AffectiveInterface` class.

The sensitivity of the affective predictions can be selected by the developer simply by demanding that a certain number of consistent predictions in a row occur before their system acts upon the affective information. By increasing this buffer the application developer can filter out one off affect changes, and artefacts caused by muscle movement and other noise, ensuring that any prediction received has been consistent over a certain period of time. This is achieved by calling the `getConsistentPrediction(method)` which allows the number of hits in a row (consistent predictions) required to be specified. This proved to provide a simple and effective method of sensitivity control and noise filtration.

Chapter 7: Evaluation & Conclusion

7.1 Evaluation and Effectiveness of Demo Application (Affective MP3 player)

In order to test and demonstrate the effectiveness of the developed interface, a sample demo application was developed. The demo application consisted of a simple MP3 music player, which used 2 interfaces, a standard keyboard and of course the Affective Choice Interface using the electrode placement outlined in Figure 6-12. The demo application had all the usual functionality of a standard MP3 player, volume, play, pause/resume, and skip song, however this Affective MP3 player implementation also had the capability of building training data, creating affective models and viewing affective signal classification predictions.

The affective interface also allowed for some extra features - for instance, a brain controlled mechanism was included that allowed the user to control the pause/resume function of the player using only conscious thought. This SVM model which controlled this function was trained to recognise changes in the arousal level of the user. Alpha brainwave frequencies evident when the user closed their eyes and relaxed, clearing their mind were recorded and compared to normal eyes open, focused, and alert states. Only when all 3 affective relaxation conditions occurred would the player switch to paused mode. For instance, if the user closed his/her eyes but didn't clear his/her mind (was attempting arithmetic or was focused on a problem) the affective interface would not give a consistent reading, and playback would continue.

Another SVM model was trained to classify differences in valence level of the user. Affects evident in the user's beta brainwave patterns when they were happy (smiling) as opposed to when they were sad (frowning) were measured and modelled with the SVM. This model was applied to control the choice of song, so that whenever the user chose to skip a song or when the end of a song was naturally reached, the

affective state of the user would be read, and an affective choice would be made on their behalf whether to play a happy song or a sad song. This informed choice could be made without explicit interaction by the user, and was based on the most current affective state of the user. This affective knowledge allowed the system to make a desirable choice on behalf of the user, by simply accessing the mood of the user.

7.1.1 Evaluation

In order to evaluate the effectiveness of the Affective Choice Interface System, seven demonstrations of the affective MP3 application were made to third party participants. These participants watched and prompted a trained user to control the system, pausing/resuming playback on cue. During these demonstrations, which on average lasted 9.4 minutes, the participant was presented with and asked to fill out a questionnaire (See Appendix Table 0-3: Demonstration Questionnaire). While using the feedback window of the demo application, the participant was asked to prompt the user to smile and induce a happy emotion, or to frown and induce a sad emotion, while the feedback window outputted either ones or zeros (1 trained to happy, and 0 trained to sad). The participants were then asked as to what percentage range they felt the system predicted the user's mood correctly? They responded on average in the range of 75% to 94% accuracy for this valence test.

The MP3 player was then started and the participants were asked, on 10 occasions, to prompt the user to pause and resume playback, estimating how many seconds the user took on each attempt. Results from this test showed that an average of 4.7 seconds was needed to cause pause/resume to be triggered by a trained user. The best values achieved in one demonstration averaged just 2.3 seconds for this test. In order to ensure that the pause/reply mechanism was not simply triggering itself, many users did not prompt the user to pause for very long periods, during which the mechanism was not triggered (apart from one occasion). Following this second test the participants were asked to state the percentage of time they felt the system was being controlled by the user, to which all participants replied in the 81-100% category, showing that the user was, indeed controlling the system using this arousal model.

To the remaining questions all participants categorised their impression of the responsiveness of the system as either good or very good and the usefulness of the system generally was regarded as either useful or very useful. One participant commented that they could see how such a system could, in the future, become pivotal in modern technology applications, especially in home and office applications.

7.1.2 Demonstration conclusion

The evaluation presented above was somewhat limited by both the number of participants and the fact that the same user was controlling the system for all of the demonstrations. Notwithstanding that it does, however, demonstrate a number of important facts. First of all it shows that the affective choice interface, whose design and implementation is outlined in this thesis, is indeed capable of measuring, modelling and predicting the affective state of a user. What's more it can be demonstrated to predict a user's affective state very accurately - up to 94% accuracy as reported by the participants. This simple evaluation also outlines the systems ability to model both valence and arousal signals from Pre-frontal EEG measurements. This ability demonstrates that the system may be able to model a whole range of affective emotions, according to Wundt's valence/activation model of emotion, allowing it to be used as a valuable interface to a potentially wide range of applications.

7.2 User tests

Two user tests were carried out on the Affective Interface System. The first user right-handed male 24, and the second user a right-handed, female 23. Both users were hooked up to the system using electrode placements outlined in Figure 6-12 : Effective EEG Sensor Placements. Both users affective EEG signals were modelled for use with the Affective MP3 demo application as outlined in 7.1. Both users were able to control the pause/resume function in a similar fashion, with models created from minimum training data (200 line vectors). The Happy/Sad valence model also could be utilised by both users receiving accurate affective predictions from the affective interface system.

This quite minimal user testing, is used to illustrate that the Affective Choice system can be easily trained to different users affective EEG signals and to show that even with only minimal training data, good affective classification can be achieved.

7.3 Conclusion

This thesis presents the successful outcomes relating to the careful research, design, implementation and proven usability of this affective choice, user interface system. The wholly achieved aim of this project was to design and build a reusable affective user interface, which could be easily reused as a component of future ubiquitous applications, and could be shown to provide an additional “emotional channel” for human computer interaction.

The research involved in the choice of EEG as the source of affective signals played a pivotal role in the success of this project. The EEG data proved to provide a very useful measure of a subject’s affective signals, so much so that it seems strange that EEG has not been exploited more often in the development of affective computing systems. The demonstrated ability of the system to recognise a user’s modelled emotional state from EEG signals recorded from the pre-frontal hemispheres of the brain also provides evidence in support of the importance of this area in the management of emotion.

This thesis also puts forward an argument for the use of affective user interfaces as a solution to the difficulties of sentient system control. As shown in Section 7.1, by providing invisible affective user interfaces, such as the affective choice system to these ubiquitous (sentient) applications, it will allow them to make desirable choices on our behalf by simply basing its decisions and actions on our affective state, or mood without the need for physical actions or explicit interaction.

7.4 Future Work

The prototype EEG based affective user interface outlined, has definite potential as a main stream user interface. There are an infinite number of applications that could benefit from the use of this system. The evaluation of the system illustrated its

ability to provide both conscious control to the user, analogous to a Brain Controlled Interface, and unconscious control, where a device or application could make an informed choice on behalf of the user based on their affective state. This “Affective Choice” ability that can be gained by any application using the affective interface system, is still, in my view, the most exciting application of the system. I feel that future work should concentrate on working towards a more invisible affective interface, for use with sentient and smart space type applications, allowing them to serve up what we need and desire without needing to ask.

13	Cheek Puffer	<i>Levator anguli oris (a.k.a. Caninus)</i>	
14	Dimpler	<i>Buccinator</i>	
15	Lip Corner	<i>Depressor anguli oris (a.k.a. Triangularis)</i>	
16	Lower Lip	<i>Depressor labii inferioris</i>	
17	Chin Raiser	<i>Mentalis</i>	
18	Lip Puckerer	<i>Incisivii labii superioris and Incisivii</i>	
20	Lip stretcher	<i>Risorius w/ platysma</i>	

Figure 0-1: Ekman & Friesen's Action Units (Ekman and Friesen 1978 - <http://www.cs.cmu.edu/afs/cs/project/face/www/facs.htm> [23])

Appendix: Source Code

```
/******  
Filename: dlldefs.h  
BrainMaster DLL extension library  
header file defining data offsets into dll memory space  
begun: 11/21/96  
    1/12/97: enlarged value blocks, added control blocks  
    1/20/97: revised Control Flag area to 0x600 from 0x500  
    7/11/97: changed frequencies to new 8-band system  
    7/14/97: added CONTROL_PARMS  
    7/14/97: added component LOW & HIGH limits  
    08/22/01 @gtw Add DLL_DATA_SIZE and remove extra defines.  
    08/28/01 tfc added defines for waveform & filtered  
    09/09/01 tfc added value blocks for stdev and nextthresh  
    11/14/01 gtw Updated IAW design review of 13 Nov 01.  
1. Added xx_DAMP_FFT_START and remove extra channel area.  
2. Added xx_FFT_SUMM_START for 32 FFT bins for 60 seconds of summary data.  
    11/27/01 gtw Updated IAW design review of 27 Nov 01  
    1. Added SIZEOF_SUMM_FFT, RT_FFT_SUMM_CTRL_START HEG_VALUE  
    2. Added AUTO_THRESH, HEG flags  
    3. Added <component>_PERCENT_TARGET values.  
    4. Updated commentary.

```

To read a value, use e.g. value = DIIFunc(LT_VAL_START+THETA_VAL, 0);
NOTE: TOTAL IS ONLY 16K. DO NOT GO ABOVE 3FFF THIS IS DUE TO THE 16-BIT LIMITATION.
FIRST 64K OF DLL SPACE IS DIVIDED UP AS FOLLOWS (addresses in hexadecimal): NOTE THAT ALL
ADDRESSES ARE OF 16-bit WORDS

```
0000-03FF:*****VALUE BLOCKS FOR 8 CHANNELS 1/2 K TOTAL*****  
VALUE BLOCKS CONTAIN VALUES, THRESHOLD, MAX, MIN, ETC. FOR EACH COMPONENT  
0X0000 - BEGIN 1K BLOCK ALLOCATED TO CHANNELS 1-8 VALUE BLOCKS  
0X0000 - 0x007F: 128 words: Channel 1 value block ( "Left" )  
0X0080 - 0x00FF: 128 words: Channel 2 value block ( "Right" )  
0X0100 - 0x017F: 128 words: Channel 3 value block  
0X0180 - 0x01FF: 128 words: Channel 4 value block  
0X0200 - 0X03FF: (512 words for Channels 5,6,7,8)
```

```
0400-05FF:*****LIVE FFT BLOCKS*****  
64 bytes per spectrum x 8 channels = 512 bytes  
0400-043F: CHANNEL 1 LIVE FFT BLOCK POSTED 4 PER SECOND  
0440-047F: CHANNEL 2 LIVE FFT BLOCK  
0480-04FF: Spare.  
0500-053F CHANNEL 1 DAMPED FFT BLOCK POSTED 4 PER SECOND  
0540-057F CHANNEL 2 DAMPED FFT BLOCK POSTED 4 PER SECOND
```

```
0600-09FF:***CONTROL FLAGS, PARAMETERS, AND SESSION AND CALIBRATION INFO****  
0600-06FF: 128 WORDS CONTROL FLAGS FOR REMOTE SETUP  
0700-0800: 128 WORDS CONTROL PARAMETERS  
0800-09FF: 256 WORDS SESSION & CALIBRATION INFORMATION
```

```
DO NOT USE REGIONS DEFINED BELOW  
3000-3FFF:***SUMMARY FFT AREA FOR COMPRESSED SPECTRAL ARRAY 4K TOTAL*****  
BEGIN SUMMARY FFT BLOCKS FOR 2 CHANNELS, POSTED 1 PER SECOND  
(64 bytes/second = 16 seconds per 1K, or 3.75K per minute)  
7.5K: Channel 1 FFT block 1 minute  
0.5K: TBD; reserved for control information  
7.5K: Channel 2 FFT block 1 minute  
0.5K: TBD; reserved for control information
```

```
1000-2FFF:*****LIVE EEG AREA 8K TOTAL *****  
TOTAL OF 30K FOR LIVE EEG CHANNELS 2 CHANNELS RAW & FILTERED
```

```

BEGIN LIVE EEG CHANNELS 2 seconds = 240 bytes per record
(USE 256 bytes for round numbers)
CHAN 1 RAW 256 samples
CHAN 2 FILTERED 8 x 256 samples
CHAN 1 RAW 256 samples
CHAN 2 FILTERED 8 * 256 samples
CONTROL INFO - SIZES, NUMTRACES, ETC - 128 bytes
